The Critical Potentials of Tungsten.—The erratic records usually obtained of the secondary emission of electrons from metals bombarded by cathode rays have been shown by H. E. Krefft to be connected with the presence of adsorbed films of gas. His experiments, which are described in the *Annalen der Physik* (vol. 84, p. 639), were made with a tube built entirely of metal and glass, in which a vacuum of 10^{-8} mm. mercury could be maintained, containing a tungsten target which could be heated to 1500° C. by radiation from an auxiliary filament. At the higher temperatures the breaks in the secondary emission curves were reproducible, and ratios of the secondary current to the primary current were obtained which were consistent to less than one per cent., under favourable conditions. At lower temperatures, and in general when gas was known to be present, new breaks appeared; and finally, when the gas-content became relatively large, the curves were smooth. The main critical potentials agree well with those found by Prof. O. W. Richardson and Dr. Chalklin from the study of soft X-rays, but one persistent break at about 16 volts has had to be attributed to ionisation of molecular oxygen, from which it appears impossible to free the metal, even above 1000° C.

A Polarisation Colour Scheme.—A useful miniature booklet for the waistcoat pocket has been issued by Messrs. James Swift and Son, Ltd., entitled "Polarisation Colour Scale." The contents have been drawn up as an aid to mineralogists by Drs. W. R. Jones and A. Brammall. On the inside of the cardboard cover is given a table of the birefringencies of seventy-eight mineral crystals, and two polarisation colour scales (in colour, a very good attempt at reproduction of the natural colours), one for crossed Nicols and the other for parallel Nicols, each for the first four orders of spectra. In the four little pages of text, explanations are given of the practical meaning of birefringence and of the numerical scale-values attached to the colours, and instructions are detailed for using the scale to determine the thickness of rock-sections and the birefringence of mineral crystals, either in rock-sections or in mounted grains. The method recommended for finding the thickness of a rock-slice is, first, to select some familiar colourless mineral of low birefringence, such as quartz (birefringence 0·009), represented in the slice by numerous sections; then, to evaluate in $\mu\mu$ the highest interference colour given by these sections, by reference to the scale; for thickness = (interference colour value)/(birefringence × 1000). The thickness thus given (in microns) can then be used to determine the birefringence of an unknown mineral; for the birefringence = (interference colour value)/(thickness × 1000). If the mineral be itself a naturally coloured one, allowance must obviously be made for the modification this causes in the polarisation colours.

Molecular Structure in Solution.—Various physical properties of solutions of cobalt chloride with increasing hydrochloric acid content and of hydrochloric acid alone have been determined by O. R. Howell in an attempt to investigate the change of state of the cobalt atom with increasing concentration of acid. The November number of the *Journal of the Chemical Society* contains conductivity values for such solutions, and the conclusions drawn from these results are in agreement with those obtained from previous work on other properties. As acid is added to a cobalt chloride solution, the red colour changes to blue, owing to the cobalt atom being forced out of association with six molecules of water, $Co(H_2O)_6$, in order to unite with four atoms of chlorine, $CoCl_4''$. Hill and Howell, in 1924, showed that in blue compounds the cobalt atom is surrounded by four other atoms or groups, whereas when it is surrounded by six atoms the compound is red. Howell points out that these facts can be utilised to predict, to a certain extent, the crystal structure not only of compounds containing cobalt but also of those in which a metallic atom can be replaced by cobalt. Several predictions made in this way (for example, with zinc and magnesium orthosilicates) have been verified by determination of the crystal structure.

Ionisation and Chemical Change during Slow Combustion.—The work of Dixon and others has shown that before the main combustion of a gaseous mixture occurs, there is an induction period during which slow combustion proceeds. Bennett and Mardles, in the *Journal of the Chemical Society* for December, have attempted to investigate the nature of the changes occurring during this period. They found that in the case of a system containing liquid drops (*e.g.* *n*-hexane and air) more ionisation took place and a considerably lower temperature was required for spontaneous ignition than with the corresponding vapour mixture. It is questionable whether ionisation accompanies all gaseous reactions, but ionisation was detected with various systems, although it did not occur below the temperature of initial oxidation. During the period of slow combustion, the main changes appear to be due to thermionic emission followed by the formation of centres of chemical change around the liberated ions. The presence of various 'antiknocks' (*e.g.* lead tetraethyl, iron carbonyl) causes a decrease in electron emission and in the initial chemical change, thereby delaying spontaneous ignition and also lowering the temperature at which slow combustion begins.

Insulin and Carbohydrate Metabolism.

ALTHOUGH the main outline of the action of insulin on the metabolism of carbohydrate is now fairly clear, the actual details of the chemical transformations occurring in the synthesis and combustion of sugar in the body are still only known in part. The view that insulin transforms glucose into some reactive form, although still maintained by some investigators, has not been confirmed by others. Either there is a failure to find any change in the rotation of the glucose under the influence of muscle tissue and insulin (A. B. Anderson and A. Carruthers, *Biochem. Jour.*, vol. 20, p. 556; 1926), or discrepancies between the polarimetric and copper reduction values of the extracts examined are considered to be explicable rather on the basis of the presence of other optically active or reducing substances in addition to the glucose (H. F. Holden, *ibid.*, p. 263, and G. S. Lund and C. G. L. Wolf, *ibid.*, p. 259). Anderson and Carruthers have also found that the polarimetric value of dialysates or extracts of blood varies according to the reaction of the solution at the time of estimation.

It appears certain that phosphorus plays an essential part in the utilisation of glucose; and the formation of a hexosephosphate may be regarded as an essential link in the chain, probably both to synthesis and degradation. An exception, however, appears to be provided by blood, the corpuscles of which break down, *in vitro*, glucose into lactic acid, without the intervention of the phosphorus molecule (J. T. Irving, *ibid.*, p. 1320). The reduction in the blood-sugar under the action of insulin is always accompanied by a parallel reduction in the inorganic phosphorus, which, however, is later excreted from the body, any hexosephosphate formed not being stored but rapidly broken down again.

The development of convulsions when the blood-sugar has fallen to a low level, and their abolition by the administration of glucose, has provided a useful means of investigating further the details of carbohydrate metabolism by observing what compounds have the same favourable effect as glucose. The convulsions appear to be caused by disturbances in equilibrium, the symptoms being similar to those observed after unilateral labyrinth extirpation or other lesion to the vestibular apparatus (W. Russell Brain, *Quart. Jour. Exp. Physiol.*, vol. 16, p. 43; 1926). Thus the animal (rabbit) holds its head rotated to one side, and the whole body may be rotated on the pelvis. Later, rolling movements occur towards the side to which the head is rotated, sometimes also to the opposite side. On the other hand, the preliminary symptoms of apprehensiveness and shying at the movement of an observer suggest a heightened irritability of the whole of the central nervous system, which perhaps one might suggest to be correlated with the fall in the sugar of the blood.

The brain, and presumably also the rest of the nervous system, depends for its glucose upon that brought to it in the blood; although reducing substances are present in the brain tissue, they appear to consist chiefly of creatinine and pentoses (Barbara E. and E. G. Holmes, *Biochem. Jour.*, vol. 19, p. 492; 1925; and vol. 20, p. 595; 1926). These authors, in their investigations into the metabolism of the brain, have found that this tissue forms lactic acid from glucose in the absence of oxygen, and that the acid is removed if oxygen is afterwards admitted. Examination of rabbit's brains *post mortem* shows that they contain lactic acid, the amount of which does not increase on anaerobic incubation unless glucose is also present. From their series of experiments, the conclusion may be drawn that the amount of lactic acid found in the brain *post mortem* depends on the level of the blood-sugar at the time of death, and is roughly proportional to it: thus it is increased following the administration of an anæsthetic and decreased after an injection of insulin. It bears no relationship to the reducing substances in the brain, which, as we have seen, are not glucose, or apparently to the glycogen, which remains remarkably constant after a variety of experimental procedures, such as depancreatisation or the injection of a convulsive dose of insulin.

The formation of lactic acid from the blood glucose must be a highly active process, since it appears to be complete in the few minutes elapsing between death of the animal and removal and cooling of the brain: in the rabbit the amount found is of the order 0·1 gm. per cent. Insulin has no direct effect on the lactic acid metabolism of the brain, but influences it solely by producing hypoglycæmia: moreover, following depancreatisation, the brain can convert both blood and added glucose to lactic acid under anaerobic conditions and remove it again in the presence of oxygen, and to the same degree as a normal brain (*ibid.*, vol. 19, p. 492; 1925, and p. 836; vol. 20, p. 1196; 1926; and vol. 21, p. 412; 1927).

It appears, then, that insulin plays no part in the conversion of glucose to lactic acid and the subsequent removal of the latter in the brain as in skeletal muscle, but the work throws no light on why hypoglycæmia should produce convulsions: the lactic acid in the brain tissue itself is reduced when the blood-sugar falls, but, following the convulsions, the blood lactic acid increases, owing to the escape into the circulation of some of the acid set free during the violent muscular movements.

Since Herring, Irvine, and Macleod investigated the remedial effect of various sugars upon insulin convulsions (*Biochem. Jour.*, vol. 18, p. 1023; 1924), numerous other investigators have studied the same problem, using a variety of sugars or their possible metabolites in the hope of discovering some of the stages through which carbohydrates pass in their metabolism in the body. Recovery has been produced by the administration of glucal (Winter) and dihydroxyacetone (Kermack, Lambie and Slater, Laufberger, Hewitt and Reeves, Markowitz and Campbell, etc.), whilst the following compounds have been found to be inactive: glucosan and desoxyglucose (Winter), methyl glyoxal, lactic acid, glycerol, sodium citrate and pyruvate, and rhamnose (Lambie and co-workers), hexosedi- or mono-phosphate (Marks and Morgan), glyceric aldehyde (Hewitt and Reeves), and glucosone (Hynd) (L. B. Winter, *Biochem. Jour.*, vol. 20, p. 668; 1926; and vol. 21, p. 54; 1927; W. O. Kermack, C. G. Lambie and R. H. Slater, *ibid.*, vol. 20, p. 486, and vol. 21, p. 40; Lambie and Frances A. Redhead, *ibid.*, vol. 21, p. 549; H. P. Marks and W. T. J. Morgan, *ibid.*, vol. 21, p. 530; V. Laufberger, *Publ. de la Faculté de Médecine*, Brno, Czechoslovakia, vol. 4, p. 1; 1926; J. A. Hewitt and H. G. Reeves, *Lancet*, vol. 2, p. 703; 1926; J. Markowitz and W. R. Campbell, *Am. J. Physiol.*, vol. 80, p. 548; 1927; A. Hynd, *Proc. Roy. Soc.*, vol. 101, B, p. 244; 1927).

Various points of interest emerge from this work. Glucal is presumably effective owing to the similarity of the molecule to that of glucose. More interest attaches to the place of dihydroxyacetone in carbohydrate metabolism. Laufberger has shown that its behaviour in the body is the same as that of glucose (*Pub. de la Faculté de Médecine*, Brno, Czechoslovakia, vol. 2, p. 83; 1923–24), and Lambie and his co-workers have adduced evidence indicating that it acts by being directly oxidised and not by being converted into glucose first: in which case they suggest that the reaction which is facilitated in the organism by insulin, and fails to proceed satisfactorily in the diabetic, is the transformation of glucose into dihydroxyacetone. Thus they have found that in the decerebrate eviscerated preparation, the latter will not maintain the blood-glucose at a constant level when infused, nor does it accumulate in the blood, the inference being that it is immediately oxidised: in other experiments its administration has failed to give so marked a rise in the blood-sugar as that of glucose itself: it raises the respiratory quotient and increases the metabolism more quickly and to a greater extent than glucose: and the fall in the inorganic phosphate of the blood parallels the intensity of the metabolic change, so that it appears that dihydroxyacetone causes a more rapid formation of the phosphoric acid ester than glucose.

These authors suggest that the reactions which occur may be similar to those postulated, from theoretical considerations, by A. L. Raymond (*Proc. Nat. Acad. Sci.*, vol. 11, p. 622; 1925). Glucose reacts with phosphoric acid to form a hexosemonophosphoric ester, which then splits into a molecule of triose and one of triosephosphate: two molecules of the latter condense to form a hexose diphosphate, which is hydrolysed back to hexose and inorganic phosphate. The triose may be dihydroxyacetone itself or closely related to it. In a further discussion, Lambie points out that lævulose, like dihydroxyacetone, is both more easily oxidised and a better glycogen former than glucose, yet only glucose can be obtained from glycogen on hydrolysis: it is therefore possible that dihydroxyacetone may be a common intermediary between lævulose and glucose and glycogen. Lævulose, however, does not cause recovery from insulin hypoglycæmia so readily as glucose or dihydroxyacetone: possibly it may be converted into the latter without the aid of insulin, being more closely related to it than glucose. In insulin hypoglycæmia, however, the conversion of glucose into dihydroxyacetone under the influence of the excess of insulin might be even more rapid than the transformation of lævulose, so that glucose would be more effective in causing recovery than the latter.

This hypothesis of the mechanism of action of insulin and of the rôle of dihydroxyacetone in metabolism has, however, been controverted by Markovitz and Campbell, who maintain that this compound is not a normal metabolite of glucose, but must be converted into the latter by the liver before the body can make use of it, and adduce experimental evidence in support of this view. The ultimate decision between these two views must be withheld until further work, which will be awaited with interest, has been carried out on the rôle of dihydroxyacetone in carbohydrate metabolism.

In conclusion, attention may be directed to some interesting observations which may possibly lead to a satisfactory explanation of the cause of insulin convulsions. Mention has been made of the fact that methylglyoxal cannot produce recovery from them: Lambie and his co-workers have also noticed that after an injection of this compound, glucose or dihydroxyacetone may also be ineffective: in other words, methylglyoxal appears to exert some toxic action on the animal. Hynd has gone even further, and observed that an injection of glucosone (a body closely related to glucose from which methylglyoxal might possibly be derived) produces a condition similar to insulin hypoglycæmia, which, however, differs from the latter in that glucose cannot bring about recovery. He suggests that insulin may cause the production of glucosone from glucose in the body.

These observations suggest that the convulsions are caused by some intermediary metabolite in the combustion of glucose: it appears reasonable to suppose that this compound is always being formed in small quantities in the body, but is immediately further broken down. Following an injection of insulin, the amount produced is considerably increased and the oxidising mechanism fails to keep pace with this increased production, so that the compound set free in the body is enabled to exert its toxic effects. In this connexion the work of Dakin and Dudley may be recalled: they found that most tissues contained an enzyme, glyoxalase, which was capable of converting methylglyoxal into lactic acid. However, the relationship between the curative effect of an injection of glucose or dihydroxyacetone upon insulin convulsions, and the possible presence of glucosone or methylglyoxal in excess as their direct cause, appears to require further investigation before one of the different hypotheses outlined above can be considered definitely established.

Marine Biology in Ceylonese Waters.

Details of the marine biological research carried out by the Ceylon Government are contained in the Administration Report of the Government Marine Biologist for 1926. (Part 4: Education, Science, and Art (F), by Dr. Joseph Pearson. Pp. F29. Colombo: Government Record Office. 65 cents.) In this report there is an account by Mr. A. H. Malpas, the assistant marine biologist, on the present state of the pearl oyster, the window-pane oyster, and the chank (a gastropod, *Turbinella pyrum*, Linn.) fisheries. It would appear that there is no likelihood of a large pearl oyster fishery for at least four years, whereas an experimental fishery on the lines advocated by Dr. J. Pearson, the marine biologist, may be held in 1928. The essence of the new system is the elimination of the sale of oysters to the public, by which means all the pearls would come into the hands of the Government.

The window-pane oyster fishery at Lake Tamblegam in 1926 was very successful. Although the Government received a revenue of only Rs.18,000.0 for two million oysters, it is stated that the lessee's returns from the fishery were between one and two lakhs of rupees, but the sum was more probably nearer Rs.50,000.0. There is a curious anomaly in the control of the chank fishery in the Palk Strait. On the Indian side the fishery is under the control of the Madras Fisheries Department, and hence the Government made a net profit of Rs.46,367.0.0 in 1922–23 on 466,540 chanks. On the Ceylon side chank fishing is open to all comers, and the only revenue that accrues to Government is that derived from the export duty. In 1923, the Ceylon Government made a profit of Rs.12,065.0 on 2,419,786 chanks. From these figures it is clear that although the Ceylon chank fishery is about five times as large as the Madras fishery, yet its value as a Ceylon Government asset is almost negligible.

A considerable amount of fisheries research has been carried out by Mr. A. H. Malpas and Mr. M. Gomez. It is very gratifying to note that, as a direct outcome of the trawling experiments carried out by the Government Marine Biology Department, a company has been registered in Colombo to modernise the local fishing industry. There is every hope that this new enterprise for commercial exploitation of Ceylon waters will be successful. The part of the report that should interest every Ceylonese is that entitled 'Miscellaneous.' Under this heading, the author states that a sum of Rs.8,048,297.0 was collected in 1925 as import duty on dried fish goods. Hence any step that could be taken towards the organisation or the development of local curing should be encouraged. Towards this aim some useful experiments have been carried out, and so far with great success.

Work on fresh-water fishes has been mainly carried out by Mr. P. E. P. Deraniyagala, the second assistant marine biologist. He has commenced on an atlas of fresh-water fishes of Ceylon, which it is hoped will be useful to both laymen and naturalists. In addition to this he records that a fish, *Lutianus rivulatus*, locally known as *Baddau*, has an inshore migration lasting for a few weeks in May, and suggests that it spawns in deep water far from land.

The marine superintendent, Lieutenant-Commander E. L. Pawsey, is making some useful investigations to locate the exact position of the pearl banks, beacons, etc., as the existing charts are found to be almost useless.

The Marine Biology Department of the Ceylon Government should be congratulated on the amount of useful work it is carrying out towards the development of the resources of the country.

University and Educational Intelligence.

Oxford.—The honorary degree of Master of Arts has been conferred on Mrs. Florence Joy Weldon, widow of the late Dr. W. F. R. Weldon, professor of zoology, who had recently received the thanks of the University for her gifts of pictures.

Owing to need for further space in Dr. Lee's department of inorganic chemistry required by workers engaged on research in physical chemistry, a special research room is to be added at a cost not exceeding £2800 from the Government grant.

Preparations are being made for an expedition this year to the south-west coast of Greenland under the leadership of Dr. T. G. Longstaff, and a grant of £50 has been voted thereto by Congregation. The main purpose will be the study of the ecology of the Arctic fauna and flora in that region. Similar expeditions were undertaken by members of the University in 1921 to Spitsbergen, and in 1923 and 1924.

Mr. F. G. Tryhorn, lecturer in physical chemistry in the University of Sheffield, has been appointed professor of chemistry in University College, Hull.

Dr. R. K. Butchart, lecturer in mathematics in the University of St. Andrews (University College, Dundee), has been appointed to the chair of mathematics at Raffles College, Singapore.

The trustees of the Mary Ewart fund are offering a travelling scholarship, value £200, for one year, to past and present students of Somerville College, Oxford. Particulars may be obtained from Mrs. T. H. Green, 56 Woodstock Road, Oxford.

Applications for the Government Grant for scientific investigations, in connexion with the Royal Society, must be received on a prescribed form by the Clerk to the Government Grant Committee, Royal Society, Burlington House, W.1, by, at latest, Mar. 31.

An examination for the following scholarships offered by the Household and Social Science Department of King's College for Women, Campden Hill Road, W.8, will be held on May 10: the "Carl Meyer," value £80, and tenable for three years; the "Minor College," value £40, and tenable for three years. Particulars may be obtained from the Secretary of the College.

Examinations for the award of Tate and Morgan scholarships in engineering, science, domestic science, hygiene, and art, at Battersea Polytechnic for the session 1928–29, will be held on Tuesday, June 12, and succeeding days. The scholarships vary in value from £20 to £30 per annum with free tuition, and are tenable for two or three years. The latest day of entry is April 21.

An excursion for geographers and other workers in open-air sciences, starting on July 27, is being arranged for field-work in southern Spain and in the Rif. The party will stay first at Algeciras, and then at Tangier. An attempt will be made at comparative regional surveys of the northern and southern boundary areas of the Straits of Gibraltar. Particulars may be obtained by sending a 2d. stamp to Mr. Valentine Davis, Cheshire County Training College, Crewe.

The Ella Sachs Platz Foundation for the Advancement of Scientific Investigation is inviting applications for grants in aid of research. Preference is given to research in medicine and surgery or branches of science bearing on these subjects, and particularly to work on any single problem. In previous years, the general subject of chronic nephritis has received support, and, in a lesser degree, internal secretion and injection. Last year, twenty-four grants were made, seventeen of them being to workers outside the United States. Applications must reach Dr. Joseph C. Aub, Massachusetts General Hospital, Boston 14, Massachusetts, before May 15.

"The Quality of the Educational Process" is the title of a comparative study of education in the United States, England, France, and Germany, undertaken by Dr. W. S. Learned for the Carnegie Foundation for the Advancement of Teaching and published in the Foundation's recent annual report. Dr. Learned is concerned to reveal the defects in his own country's systems and to show how they may be remedied by applying the lessons of the hard-won experience of European nations. In three important respects he finds the European systems superior to the American. The general foundation is laid compactly in a single sequence including nearly the entire adolescent period and, as a consequence of this thorough preparation, the student's general education continues inevitably after he has embarked on his more advanced and vocational studies. Secondly, the principle of continuity in the main threads of the educational material is respected, long periods of work being adjusted to clearly defined aims, the material being constantly revised from advancing points of view, and the student's attention being kept fixed upon the quality of his thinking rather than on merely getting through set tasks. Thirdly, the final, usually external, examination at the end of each considerable stretch of work invigorates the whole process, constituting not merely a satisfactory test of intellectual power but also an indispensable instrument wherewith to develop it. With these three merits—compact foundation, continuity of subject matter, and judicious use of examinations—are contrasted the corresponding defects of the American system. Specially noteworthy is the praise bestowed on the place assigned in Europe to examinations. This paper, and a previous paper by the same author on secondary education in the United States and in Europe, are published separately as *Bulletin* No. 20 of the Foundation.

Calendar of Customs and Festivals.

February 20.

COLLOP MONDAY: also, sometimes, Shrove Monday. The period of merrymaking and feasting before Shrove Tuesday and the beginning of Lent known as Shrove Tide or Carnival, as the latter name is intended to suggest, bade farewell to meat before the entry upon the Lenten or spring fast. In the north of England this survived in the custom of eating collops (slices of bacon or salted meat) with eggs as one of the dishes at dinner on the Monday before Ash Wednesday.

February 21.

SHROVE TUESDAY. The day for the confession of sins or shriving, also the day on which the merrymaking of carnival culminates. In England Shrove Tuesday was a holiday and occasion of merrymaking both before and after the Reformation. The summons to confession was by the ringing of a bell, which continued to be rung after the Reformation but was known as the Pancake Bell. In England the eating of pancakes and the tossing of the pancake in Westminster School are now practically the only survival of the Shrove Tuesday feast and its ritual.

As a holiday Shrove Tuesday was especially associated with the freedom of the apprentices and workers, who jealously guarded their privileges of "doing what they list." They also joined in the customary activity in searching out and carting women of ill fame and their male companions at this time. The licence permitted to the 'prentices may be compared with the privileges allowed school children in some parts of Scotland on this day, which are similar to those permitted at Candlemas. At Bromfield, in Cumberland, the scholars of the Free School used to bar out the schoolmaster for three days. The articles of capitulation specified the times of study and play in the coming year, and stipulated the immediate playing of certain games—a cock-fight and a football match.

Cock-fighting, one of the most popular of the amusements of Shrove Tuesday in England, was also practised in Scotland, especially by schoolboys. Cock-throwing or baiting (sometimes hen baiting) was also widely practised, when sticks were thrown at a cock tethered to the ground. Sometimes two metal cocks were used in a game in which missiles of lead were thrown at the cocks by opponents, each standing behind his own bird. Cock-throwing has been explained as an expression of the hostility of Saxon and Dane, or of our enmity with the French, but the cock is almost certainly a substitute for a human victim.

In Wales such hens as did not lay eggs before Shrove Tuesday were thrashed by a man with a flail, who received for his pains any hen which he killed.

Football was an important feature of the Shrovetide observance, and in nearly every town or village the streets were the scene of a vigorous and sometimes violent game. The contest was usually between two wards of the same town, or two towns or villages. In so far as it was a ritual observance, judged by analogy, it represents the struggle between winter and spring.

At Ludlow the contest took the form of a tug-of-war, attended by the Mayor and corporation. In other localities, matches at battledore and shuttlecock, especially between men and women, were played.

A curious and significant custom is recorded in the *Gentleman's Magazine* in February 1779. The writer saw in a Kentish village a figure called a Holly Boy being burnt by boys. This had been made by the girls but stolen from them. In another part of the village the girls were burning an Ivy Girl which they had stolen from the boys. The representation of the two sexes warrants the inference that the figures originally represented the male and female principle in Nature. Similar male and female figures appear in the processions which are found on the Continent at this and other times of the year. Sir James Frazer gives a number of instances. In the case of the processions on or about Shrove Tuesday, the significant feature is that the human figure, which is the central object of the celebration, is either torn to pieces or burnt. Sometimes in the latter case the fertility of the crops in the coming season is prognosticated by the height of the flames. In this custom of 'burying the Carnival,' it may be taken that the lay figure is the surrogate of a human victim who represented the god of vegetation. Similarly, the *bœuf gras* of the *Mardi Gras* celebrations in France is the spirit of fertility in flocks and herds.

In Roman Catholic countries the celebration of Carnival has generally survived with greater vigour than in the Protestant. Certain features are crucial. It is a period of freedom or licence. Disguise is worn which, like the skins worn by those who took part in the Lupercalia, may be either a protection against evil spirits, or an attempt at assimilation to the deity. Finally, there is usually some personification, human or animal, around which the festival centres.

February 22.

ASH WEDNESDAY. PULVER WEDNESDAY (*Dies Pulveris*). The opening day of the Lenten fast takes its name from the custom of marking each member of the congregation in church with the cross in ashes which have been blest by the priest. The ashes should be those of the palms used on Palm Sunday in the previous year. There is a reference to the practice in Anglo-Saxon times, but it was abandoned in England at the Reformation.

It is said that originally Lent did not begin until the following Sunday, but that Ash Wednesday and the succeeding days were incorporated in the observance to equalise it with the forty days' fast of Our Lord. It is, at least, true that after the solemn service of the day was over, the remainder was given up to merrymaking similar to that of Shrove Tuesday. Sometimes and in some places this included the procession, in which a figure was carried and afterwards destroyed. One such is recorded from Marseilles. Similarly, in England, Jack-a-Lent, a lay figure made from an old suit of clothes stuffed with straw, was carried in procession, pelted with sticks, and afterwards pulled to pieces.

In Germany it is said—the exact locality is not recorded—that the youths dragged the maidens, accompanied by a fiddler, in a cart until they reached some lake or river 'and there wash them favouredly.' Similarly, in England the Fool Plough, which formed part of the Ash Wednesday observances, and was drawn by youths while the girls sat on it, also ended its course in a pond—a piece of horse-play which had degenerated from a rain or fertility charm.

As usual on such occasions, children begged from door to door with an appropriate song, the custom being known as 'clacking,' from the fact that they carried pieces of wood which they clacked before the door, hoping to receive pieces of bacon for a feast. If they failed they stopped the keyhole with mud. It is also recorded that in the evening boys used to run along carrying firebrands and torches. In Dijon on the first Sunday in Lent, known as Firebrand Sunday, large bonfires were lit in the streets, a custom derived, it is said, from the practice of carrying lighted torches of straw to drive away 'badder' from the earth—in other words, evil spirits.

Societies and Academies.

London.

Royal Society, Feb. 9.—**O. W. Richardson**: On the extraction of electrons from cold conductors in intense electric fields. The attraction of an electron by its mirror image in a conductor is treated as a Schrödinger wave problem. The sharpness of the photo-electric effect at a metal surface is accounted for. A formula is obtained for the field currents from cold conductors, which agrees well with the experimental data. The result implies that electrons are being generated at a rate proportional to $(\psi\bar{\psi})^{\frac{1}{2}}$.

R. H. Fowler: The restored electron theory of metals and thermionic formulæ. This note amplifies the recent work of Sommerfeld on the electronic theory of metals by applying his ideas to thermionic phenomena. The equilibrium state of an assembly consisting of a heated metal and an atmosphere of free electrons is calculated. It appears that the vapour pressure has twice the commonly accepted value owing to the two orientations of each electron. This result is then applied to the theory of thermionic emission, and gives values in excellent agreement with the best observations.

R. H. Fowler: The photo-electric threshold frequency and the thermionic work function. The old equation for the saturation current required assumptions for which there is no justification. Sommerfeld's theory of metals leads quite simply to the existence of a sharp photo-electric threshold frequency ν_0 and to the equality of this $h\nu_0$ with the thermionic work function χ. These points have been recently considered by O. W. Richardson, but in a more elaborate manner which appears capable of simplification.

P. A. M. Dirac: The quantum theory of the electron. In order to make the quantum theory, when applied to atomic structure, agree with observation, one has had to assign to each electron a spin and a magnetic moment. This is not necessary; agreement with observation can be obtained without arbitrary assumptions by a correct relativistic application of the general quantum theory to a point-charge electron. The Hamiltonian function on which the present theory is based is linear in the energy and momentum. The spinning electron model, applied in the previous non-relativistic way, is justifiable for many purposes. The motion of an electron in a central field of force is worked out, and the energy levels obtained are shown to be the same as those given by the model in the first approximation for a Coulomb law of force.

H. T. Flint and O. W. Richardson: On a minimum proper time, and its application to (1) the number of the chemical elements, (2) some uncertain relations. The existence of a minimum proper time h/m_0c^2 is deduced by a method which is independent of the assumptions about the metrics of space and time used previously. This leads to an upper limit $\left(\frac{n}{n+1}\right)^{\frac{1}{2}}c$, on the velocity of an electron in an atom in an orbit of total quantum number n. This involves an upper limit (97) on the atomic number of any chemical element and also an upper limit on the quantum number of an intranuclear orbit. This limit is a function of the atomic number of the nucleus.

H. Jeffreys: Some cases of instability of fluids. The problem of the instability in a liquid produced by heating below is rediscussed by a formally accurate method. Where the fluid is enclosed between two perfectly conducting solid boundaries, the honeycomb structure is not developed when the liquid is flowing, being replaced by a division into long strips. There is a formal analogy between this problem and G. I. Taylor's problem of the stability of liquid between two rotating cylinders. In atmospheric problems the earth's rotation will have a considerable effect in modifying the motions produced by excessive heating below; this will probably be in the direction of making the departures from the adiabatic gradient needed to cause instability greater than in the absence of rotation (though they will still be very small) and of confining the ascending currents to regions of smaller horizontal extent.

H. A. Wilson: The emission of light by flames containing sodium and the absorption of light by mercury vapour. It was shown by Gouy in 1879 that the intensity of the light from a sodium flame is proportional to the square root of the mass of sodium in the flame per square cm. of area, perpendicular to the direction of the light emitted. This result can be explained by assuming that the sodium atoms absorb and emit light like simple damped oscillators. The absorption of mercury resonance radiation by mercury vapour can be explained in the same way by assuming that the mercury atoms absorb the resonance radiation like simple damped oscillators.

C. N. Hinshelwood and H. W. Thompson: The kinetics of the combination of hydrogen and oxygen. An examination has been made by a static method of the combination of hydrogen and oxygen, at constant temperature and volume, from the region of purely catalytic surface reaction up as nearly as possible to the point of explosion. In the last fifty degrees of this range a reaction, approximately of the fourth order, comes into prominence; it is strongly autocatalysed by steam, and has a high temperature coefficient. The normal positive catalytic effect of the walls of the reaction chamber gives place to a negative effect, which may be due to the catalytic destruction of an autocatalyst for the main reaction, or the interruption of 'reaction-chains,' or to both causes. It is concluded that the reaction measured is the true gas reaction between hydrogen and oxygen.

E. T. Copson: On electrostatics in a gravitational field. Prof. Whittaker has recently discussed the effect, according to the general theory of relativity, of gravitation on electromagnetic phenomena. In particular, he has considered electrostatics in gravitational fields of two kinds, namely, those specified by the quasi-uniform metric and by Schwarzschild's metric. Algebraic expressions for the potential of an electron in these gravitational fields are now obtained by the use of Hadamard's theory of 'elementary solutions' of partial differential equations. The expression for the potential in the quasi-uniform field is the same as that obtained by Prof. Whittaker, who used entirely different methods.

W. R. Brode: The analysis of the absorption spectrum of cobalt chloride in concentrated hydrochloric acid. The principal absorption band, between 720 and 850 $\mu\mu$, consists of at least seven component bands. By different mathematical methods of analysis, the observed curve is resolved into seven similarly shaped components. There is a constant frequency difference between each of these components, and this frequency difference is the highest common factor of the frequencies of these component bands. There is apparently a definite relation between the odd and even numbered multiples or component bands and their relative intensities of absorption.

Society of Public Analysts, Jan. 11.—**J. R. Nicholls**: Determination of small quantities of benzoic acid and cinnamic acid, with some notes on the colorimetric determination of salicylic acid. The method of determining benzoic acid is based on its partial oxidation, in a constant proportion, to salicylic acid by means of hydrogen peroxide in the presence of ferric chloride, and colorimetric determination of the salicylic acid under specified conditions. Cinnamic acid may be determined by first oxidising it quantitatively to benzoic acid.—**L. E. Campbell**: Report of the Preservatives Determination Committee of the Chemists of the Manufacturing Confectioners' Alliance and of the Food Manufacturers' Federation, on the determination of sulphur dioxide in foods. A normal procedure and an apparatus have been devised, and details of standard volumetric and gravimetric determinations are given, together with details of the treatment required in certain special cases, such as starch, gelatin, meats, dried fruits, etc.—**J. W. Black** and **B. J. W. Warren**: Notes on the effect of other reducing substances on the determination of SO_2. In some cases (*e.g.* glucose and gelatin) the interference of other reducing substances is negligible, but in others (nutmeg, mustard, ginger, etc.) it is considerable, and a time limit must therefore be set to the distillation period.—**H. R. Jensen**: (1) Rapid estimations of sulphites by alkaline liberation, or extraction, and titration. The sulphite content of certain products, such as glucose syrup and cornflour, may be satisfactorily determined by direct extraction followed by titration with iodine. (2) Barium sulphate losses in gravimetric estimations. Too low acid concentration favours adsorption of barium chloride; hence it is desirable to add the reagent in a very fine jet, and to have an excess to reduce the solubility of barium sulphate and the adsorption of alkaline sulphate.—**Osman Jones**: Determination of sulphur dioxide in sausages. On the addition of sulphite to sausages there is an immediate loss of sulphur dioxide, so that the amount found is invariably lower than that added A method of vacuum distillation is described, which gives results agreeing well with those of the Committee's standard method.—**H. M. Mason** and **G. Walsh**. Note on the oxidation of sulphites by air. Carbon dioxide must be quite free from oxygen if used in a lengthy sulphite distillation. Removal of the adsorbed air from the foodstuff by the use of a vacuum before the heating will prevent oxidation losses, but good results are also obtained by extremely rapid heating and distillation.—**H. M. Mason**: Note on the titration of dilute sulphite solutions with standard iodine solutions. The low results obtained when sulphite solutions are titrated with iodine are due to oxidation and to the escape of sulphur dioxide set free by the hydriodic acid formed during the titration, the latter being responsible for 70 per cent. of the loss.—**A. W. Knapp** and **R. J. Phillips**: Determination of sulphur dioxide in fatty substances. In rancid fats free from sulphur dioxide, volumetric determinations show an apparent content of sulphur dioxide; hence only the gravimetric process should be used in such cases.

Royal Anthropological Institute, Jan. 17.—**R. Ruggles Gates**: A pedigree study of Amerindian crosses in Canada. Crosses between French and Indians began in Ontario about 1660. The present study concerns interrelated pedigrees extending through six generations from crosses involving Cree and Ojibway Indians on one hand and French, Scotch, and English on the other. Pedigrees and ancestry of many individuals of mixed blood were obtained, with photographs of persons having many different degrees of Indian blood. The inheritance of features was studied as well as eye-colour, skin colour, and hair characters. Individuals of three-sixteenths Indian ancestry were found having essentially blue eyes and at least one factor for skin pigmentation. It is concluded that the Indian probably has more than two factors for skin-colour, and that certain of these factors are independent of certain factors for eye-colour. Independent segregation of genetic factors was found in several families. People with one-sixteenth Indian blood and distinct eye pigmentation showed the presence of an undilutable factor for skin colour. There is evidence that certain tribes probably have fewer factors for skin colour than others. This appears to be the first attempt to apply genetical pedigree methods to the study of the results of interracial crossing in man. There is abundant scope for the application of this method to anthropological crosses in many parts of the world.

Royal Meteorological Society, Jan. 18.—**Hugo Hergesell**: The observation of clouds, with special reference to the safety of aviation (*v.* NATURE, Jan. 28, p. 143).—**Sir Gilbert Walker**: World weather. Comparisons by graphical methods of variations of pressure, temperature, and rainfall have during the past half century brought to light a number of relationships between conditions at places separated by considerable distances; these have in recent years been studied systematically by taking 30 centres widely distributed over the earth and calculating by statistical methods the relationships between their seasonal values. It appears that there are three main oscillations or swayings: (1) the North Atlantic; (2) the North Pacific; and (3) the southern, affecting the Pacific and Indian Oceans. These relationships have obvious applications for seasonal forecasting.

Linnean Society, Jan. 19.—**C. V. B. Marquand**: The botanical collection made by Capt. F. Kingdon Ward in the Eastern Himalaya and Tibet in 1924–25. Capt. F. Kingdon Ward, travelling eastwards from Gyantse to Tsetang over unexplored ground, and crossing the Temo La to Tumbatse, entered the region in the neighbourhood of Lat. 29° 40′ N., Long. 95° E., where the most important part of the collection was made. A short distance east of Tumbatse a number of high passes over the eastern extremity of the Himalaya were traversed. On the highest of these passes, the Nam La, over a southern spur of the lofty Namcha Barwa at an altitude of 17,500 ft., a large number of alpines were collected. In Aug. 1924 an extensive collection was made around the Trasum Lake, and the Banda La, a pass over 18,800 ft., the most northerly point of the Expedition, was visited. Excluding the three genera Meconopsis, Rhododendron, and Primula, the collection comprises 446 species, including 54 new species as well as 26 new varieties. The genera most strongly represented, apart from the three above, are Saxifraga, Gentiana, and Pedicularis.—**F. W. Edwards**: Insect-collecting in the Southern Andes. The expedition described was a joint one arranged by the British Museum (Natural History) and the Bacteriological Institute of the National Department of Health of Argentina, its object being to make investigations regarding the mosquitoes and other bloodsucking flies of the Southern Andes, and to form a general collection of insects from the southern beech-forests. Two and a half months, October 1926 to January 1927, were devoted to collecting, most of the time being spent around Lake Nahuel Huapi, close to the western border of Argentina in latitude 41° S. From here the party worked their way across to the Chilean coast; the route taken was the regular one over the Perez Rosales Pass and across Lakes Nahuel Huapi, Frias, Todos los Santos, and Llanquihué, an ancient route which is now being increasingly used by tourists.

PARIS.

Academy of Sciences, Jan. 9.—**Pierre Termier**: The strata of the Aiguilles d'Arves between Lauteret and Vallouise.—**Ch. Fabry**: A phenomenon which accompanies binocular vision when the two visual images are not combined into one.—**J. S. Townsend**: The theory of high-frequency currents through gases. —**B. Hostinsky**: The probabilities relative to repeated transformations.—**Hadamard**: Remarks on the preceding note.—**Julius Wolff**: On the series $\sum\frac{A_k}{x-a_k}$.—**P. Bessonoff**: Nearly periodic meromorph functions defined in the whole plane.—**P. Fatou**: The movement of the perihelion of the planets.—**Wright**: A photograph of Jupiter, obtained at the Lick Observatory (California). The photographs were taken in approximately monochromatic light with the large 95 cm. Crossley reflector. In the first series the light had passed through a screen permitting the passage of only ultra-violet light of about λ3700: in the second series the screen is transparent only for rays about λ7600 in the extreme red. The photographs show great differences, the causes of which are discussed.—**L. Décombe**: The electrified spherical pellicules and the fine structure of the spectral lines.—**Paul Woog**: The extension of lubricants over solid surfaces.—**P. Schwartz**: A method of radioelectric direction finding applicable to geodesy. The radiogoniometric method described gives the position of emitting stations with a precision comparable with that obtained by optical methods.—**G. Colange**: The electrocapillary properties of mercury in contact with air. The capillary constant of mercury increases when it is electrified negatively and diminishes when it is positively electrified. There is a maximum capillary constant for mercury, which under the experimental conditions described corresponds to a negative potential of 15,000 to 20,000 volts.—**Marcel Dufour**: The refraction of a parallel light beam normal to a cylindrical lens.—**Pierre Brun and Jean Granier**: The dielectric properties of aqueous-alcoholic mixtures. Measurements of the dielectric capacity (high-frequency current, wave-length 50 metres) of isobutyl alcohol—ethyl alcohol—water and isoamyl alcohol—ethyl alcohol—water mixtures. The results are shown graphically. It is concluded that the Maxwell formula relating dielectric capacity and refractive index of organic liquids ($K=n^2$) should be replaced by $K=n^2+k_1$, in which k_1 is a variable, a function of the number of free hydroxyl ions in the solution.—**Mlle. Suzanne Veil**: The evolution of nickel sulphide and cobalt sulphide in the presence of water. The changes in the sulphides are followed by means of the changes in the magnetisation coefficient.—**F. Bourion and E. Rouyer**: Ebullioscopic determination of the molecular equilibria of resorcinol in aqueous solutions of calcium chloride.—**M. Tiffeneau and Mlle. Jeanne Lévy**: The comparative migratory aptitudes of acyclic radicals in the semipinacolic transposition of the phenyldialkylglycols. Their relations with the affinity capacities.—**Georges Brus**: The crystallised dihalogen derivatives of pinene.—**Paul Fallot**: The western termination of the Sierra de Cazorla (Andalusia).—**Henri Schoeller**: The stratigraphical characters of the Embrunais layer and of the outer edge of the Briançonnais layer to the north of the Pelvoux region.—**G. Mangenot**: The signification of the red crystals appearing, under the influence of cresyl blue, in the cells of certain algæ. The red crystals are the iodide of the oxonium derivative of cresyl blue, and indicate the presence of iodides. The distribution of iodides in algæ can be determined by means of this reagent.—**Bogdan Varitchak**: The nuclear evolution in *Ascoidea rubescens*.—**M. Bridel and P. Picard**: The primeveroside of salicylic acid.—**Maurice Fontaine**: The analogies existing between the effects of a tetanisation and those of a compression.—**M. Raymond-Hamet**: The action of chloralose on the sympathetic and parasympathetic.—**Jean Timon-David**: Contribution to the knowledge of the fats of insects: the butter from the insects parasitic on *Pistacia Terebinthus*. The aphides *Pemphigus utricularius* and other species of Pemphigus give about 20 per cent of their weight as a fat soluble in ether. The chemical constants of the fat are given.—**G. Lavier**: The prebasal vacuole of trypanosomes.—**Ch. Pérard**: A disease of the mackerel (*Scomber Scomber*) due to a myxosporidium, *Chloromyxum histolyticum*.—**Marage**: The nature of the deafness of Beethoven.

SYDNEY.

Linnean Society of New South Wales, Nov. 30.—**A. H. S. Lucas**: Notes on Australian marine algæ (No. 5). This paper contains (1) a list of the algæ collected at Michaelmas Cay, near Cairns, Qld., (2) Chlorophyceæ from Bowen, including records new for Australia, (3) a description of a new species of Codium, (4) notes on Caulerpa with a description of *C. Hedleyi*, (5) distributional notes on Fucoideæ, and (6) descriptions of two new species of Chondria.—**B. Bertram**: Mosquito control in the municipality of Lane Cove, New South Wales. The problem was to deal with *Culex fatigans*, breeding in natural waters polluted by house drainage. Oiling gave useful results, but channelling was equally satisfactory, more permanent, and likely to be less expensive. The widespread benefit felt from the treatment of certain creeks suggests that the range of flight of *C. fatigans* is greater than is usually supposed.—**Rev. H. M. R. Rupp**: A new Dendrobium from New South Wales and Queensland. The new species is allied to *D. Beckleri* and *D. Mortii* and occurs throughout the brushes among the foothills of Barrington Tops, N.S. Wales, and also at Tambourine Mt., S. Queensland.

VIENNA.

Academy of Sciences, Dec. 1.—**A. Müller and A. Sauerwald**: The behaviour of aluminium-triethyl under the influence of nickel catalyser at higher temperatures.

Dec. 9.—**K. Przibram**: The theory of the coloration of rock-salt by Becquerel rays; also remarks on the natural blue rock-salt. Pressure is supposed to be part cause of the colouring.—**E. Steinach, M. Dohrn, W. Scholler, and W. Hohlweg**: The biological actions of the female sexual hormone in aqueous form. A hormone oil containing extract of placenta has been prepared with a strength of 50,000 mouse-units per gram. The active substance is soluble in water to a solution of 500 mouse-units per cubic centimetre. Experiments have been made with albino guinea-pigs, making it easy to observe the reddening or hyperæmia of the mammæ. Marked effects have been produced in the early maturity of the mammæ and uterus in females which had been castrated when young. The effects of injecting water-soluble hormone are similar to the action of physiological hormone obtained by transplantation of ovary.—**E. Steinach**: Reactivation of the ovary and the whole female organism by the hormone method. Senile females of the rat are rejuvenated by the water-soluble hormone.

Dec. 15.—**K. Fritsch**: Observations on flower visiting insects in Styria, 1906.—**F. Frankl**: Topological relations of compact portions of Euclidean space to their components and application to the theory of prime ends. The results of Alexander's work on the Jordan-Brower theorem are extended.

SATURDAY, FEBRUARY 18.

NORTH OF ENGLAND INSTITUTE OF MINING AND MECHANICAL ENGINEERS (Newcastle-upon-Tyne), at 2.30.—W. Maurice: Electric Mine Lamps and Better Lighting.—Prof. W. M. Thornton: A New Gas Detecting Miners' Electric Lamp.—High Candle-power Lamps will be exhibited and explained by H. Staples on behalf of Prof. R. V. Wheeler.—*Papers open for further discussion*:—Impressions of the Canadian Empire Mining Congress, by W. C. Carr.—Further Modifications of the Correlation of the Coal-seams of the Northumberland and Durham Coalfield, by Dr. W. Hopkins.

PHYSIOLOGICAL SOCIETY (in Department of Physiology, University, Manchester), at 3.—E. Boyland and A. D. Ritchie: The Adductor Muscles of Pecten.—Prof. A. V. Hill: Recent Myothermic Experiments.—F. W. Lamb and J. V. A. Simpson: Assessment of Schoolboys by Air Force Tests.—F. W. Lamb, E. D. Portman, and G. J. Woolham: Posture Deviations of the Arm and their Reversal.—A. N. Birkett and F. W. Lamb: Balance of Ocular Muscles in Normal Subjects.—C. B. Brunton: Respiratory Responses to Interruption of Breathing and to Inflation.—Dr. J. C. Bramwell and R. Ellis: (*a*) The Tidal Wave; (*b*) Some Observations on the Action of Amyl Nitrite.—J. G. Woolham: On Correlations between Pulse and Respiratory Tests.—Dr. G. A. Clark: Pituitrin and Blood-Sugar.—H. B. Magee and B. A. Southgate: A Method for Determining the Effect of Electrolytes in the Lumen of the Surviving Gut on its Movements. (Preliminary Communication.)—B. Finkleman: Vagus Inhibition in its Relation to Ions.—Dr. A. D. Macdonald and E. D. Portman: The Diuretic Principle of Pituitary Extracts.—E. D. McCrea and Dr. A. D. Macdonald: The Action of Drugs on Entogastric Pressure.—Dr. E. C. Eaves: Calcium, Iron, and Phosphorus in Normal and Some Abnormal Brains.—M. M. Croll: Alteration in Weight of the Brain and Some Other Tissues during Formalin Fixation.—H. D. Kay: The Organic Phosphorus of the Erythrocyte.—Prof. R. J. S. McDowall: Class Experiments in Leucocytosis.—L. Berembloom and Dr. B. A. McSwiney: Reaction of Adrenaline with Relation to the H-ion Concentration.—Demonstrations:—Light Production in a Marine Animal (Cypridina), by W. R. Amberson; Apparatus for the Observation and Photography of the Skin Capillaries in Man, by G. L. Brown and F. W. Lamb; An Optical Sphygmograph, by Dr. J. C. Bramwell; Records of Sounds, by Dr. J. C. Bramwell and F. W. Lamb; The Action of Pituitary Extracts on Isolated Blood-Vessels, by E. D. Portman and Dr. A. D. Macdonald; Calcium and Vagus Threshold, by B. Finkleman; Histological Preparations showing the Innervation of Different Parts of the Human and Rabbit's Pituitary, by M. M. Croll; A New Drop-Recorder, by C. Inchley.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—H. C. Colles: Musical London from the Restoration to Handel (1660–1759) (III.).

SOCIETY OF SUPERINTENDENTS OF TUBERCULOSIS INSTITUTIONS (at 122 Harley Street), at 3.—Dr. A. N. Robertson: Open-air Treatment and Meteorological Conditions.

OXFORD UNIVERSITY JUNIOR SCIENTIFIC CLUB (in Departments of Electricity and Comparative Anatomy, Oxford University), at 8.15.—Annual Exhibition.

MONDAY, FEBRUARY 20.

ROYAL SOCIETY OF EDINBURGH, at 4.30.—E. B. Bailey: Schist Geology: Braemar, Glen Cluny, and Glen Shee.—Dr. H. H. Read: Highland Schists of Middle Deeside.—C. N. Kemp: The X-ray Examination of Coal Sections (Preliminary Note).—*To be read by title only*:—Dr. E. Henderson: An X-ray Examination of Saturated Dicarboxylic Acids and Amides of the Fatty Acid Series.—W. L. Ferrar: General Derivatives and Integrals.

VICTORIA INSTITUTE (at Central Buildings, Westminster), at 4.30.—Prof. T. G. Pinches: The Influence of the Mythology and Heathen Practices of the Canaanites upon the Hebrews.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—C. E. Shattock: Pathological Specimens in the Museum.

INSTITUTION OF MECHANICAL ENGINEERS (Graduates' Section, London), at 6.30.—Informal Discussion on The Relative Importance of Sales, Design, and Works Organisation in Engineering.

INSTITUTION OF ELECTRICAL ENGINEERS (Informal Meeting), at 7.—L. Emanueli and others: Discussion on 132,000-volt Cables.

INSTITUTION OF ELECTRICAL ENGINEERS (Mersey and North Wales (Liverpool) Centre) (at Liverpool University), at 7.30.—Dr. S. Z. de Ferranti: Electricity in the Service of Man (Faraday Lecture).

RAILWAY CLUB (25 Tothill Street, S.W.1), at 7.30.—Annual General Meeting.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—Prof. A. P. Laurie: Stone Preservation and Decay.

ROYAL SOCIETY OF ARTS, at 8.—Dr. H. Gough: Fatigue Phenomena, with special reference to Single Crystals (Cantor Lectures) (2).

CHEMICAL INDUSTRY CLUB, at 8.—Dr. F. C. Shrubsall: Mental Deficiency.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—G. Watkins: The Cambridge Expedition to Edge Island.

SOCIETY OF CHEMICAL INDUSTRY (Yorkshire Section).—Dr. F. L. Usher and others: Discussion on The Phenomenon of Wetting and its Industrial Significance.

TUESDAY, FEBRUARY 21.

ROYAL DUBLIN SOCIETY (in Science Room, Ball's Bridge, Dublin), at 4.15.—Rev. H. C. Browne: Stereoscopic Notes.—Dr. J. H. J. Poole: The Measurement of the Current flowing through a Photo-electric Cell by means of a Neon Lamp.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Prof. J. S. Huxley: The Behaviour of Animals (1).

ROYAL STATISTICAL SOCIETY (at Royal Society of Arts), at 5.15.—Dr. T. H. C. Stevenson: The Vital Statistics of Wealth and Poverty.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—Hon. Ivor Montagu: Exhibition of Photographs of the Moscow Zoological Gardens.—G. C. Robson: Observations on the Oviposition of Octopus.—Prof. D. M. S. Watson: On Some Points in the Structure of Palæoniscid and Allied Fish.—Oldfield Thomas: The Delacour Exploration of French Indo-China Mammals. II. On Mammals collected during the Winter of 1926–27.—S. Maulik: New Chrysomelid Beetles from India, with a Note on the Scales of Coleoptera.

INSTITUTION OF CIVIL ENGINEERS, at 6.

LONDON NATURAL HISTORY SOCIETY (at Winchester House, E.C.), at 6.30.—L. W. Chubb: Our Common Lands: The Story of their Preservation.

INSTITUTION OF ELECTRICAL ENGINEERS (North Midland Centre) (at Hotel Metropole, Leeds), at 7.—A. Page: Address.

INSTITUTION OF ELECTRICAL ENGINEERS (North-Western Centre) (at College of Technology, Manchester), at 7.—Dr. S. Z. de Ferranti: Electricity in the Service of Man (Faraday Lecture).

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—C. H. Kayser: A Comparison of the Norman Doorways of Yorkshire, Norfolk, and Gloucestershire.

INSTITUTION OF AUTOMOBILE ENGINEERS (Wolverhampton Centre) (at Engineering and Scientific Club, Wolverhampton), at 7.30.—C. R. F. Engelbach: Works Re-organisation to Increase Production.

INSTITUTION OF ELECTRICAL ENGINEERS (Scottish Centre) (jointly with Institution of Post Office Electrical Engineers—Scottish East Centre) (at Freemasons' Hall, Edinburgh), at 7.30.—E. H. Shaughnessy: The Rugby Radio Station.

INSTITUTION OF ENGINEERS AND SHIPBUILDERS IN SCOTLAND (at 39 Elmbank Crescent, Glasgow), at 7.30.—Dr. R. M. Brown: Fatigue of Metals: Some Effects of Cold Drawing on the Strength and Endurance of Mild Steel.

WEDNESDAY, February 22.

Royal Society of Medicine (Comparative Medicine Section), at 5.—Dr. H. P. Bayon: The Pathology of Certain Avian Diseases compared with that of Analogous Morbid Conditions in Man and Animals.

Royal College of Surgeons of England, at 5.—C. P. G. Wakeley: Investigations into the Surgical Diseases of the Salivary Glands, including their Pathology and Treatment.

Geological Society of London, at 5.30.—Dr. C. A. Matley: The Pre-Cambrian Complex and Associated Rocks of South-Western Lleyn (Carnarvonshire).

Birkbeck College Physical Society, at 6.—Prof. E. V. Appleton: The Influence of the Earth's Magnetic Field on Wireless Transmission (Distinguished Visitors' Address).

Society of Chemical Industry (Glasgow Section) (jointly with Institute of Chemistry) (at 39 Elmbank Crescent, Glasgow), at 7.—J. H. Hawley: Some Aspects of Toxicology.

Society of Chemical Industry (Nottingham Section), at 7.30.—F. H. Carr: The Methods Employed in the Preparation of Unstable Substances.

Institution of Electrical Engineers (Sheffield Sub-Centre) (at Royal Victoria Hotel, Sheffield), at 7.30.—A. Page: Address.

Glasgow University Alchemists' Club (at Glasgow University), at 7.30.—Prof. R. A. Berry: Chemistry in Relation to the Science and Practice of Agriculture.

Society of Chemical Industry (Edinburgh and East of Scotland Section) (at 36 York Place, Edinburgh), at 7.30.—Annual Meeting.

Royal Society of Arts, at 8.—Dr. H. R. Hall: The Excavations at Ur from 1919 to 1928.

Eugenics Society (at Linnean Society), at 8.—Dr. C. P. Blacker and Mrs. Marjorie Farrer: Birth Control: When is it Justified?

Folk-Lore Society (at University College), at 8.—Annual Meeting.

British Psychological Society (Medical Section) (at Medical Society of London, 11 Chandos Street, W.1), at 8.30.—Dr. G. V. Anrep: Conditioned Reflexes and Experimental Neuroses.

THURSDAY, February 23.

Royal Society, at 4.30.—Sir Leonard Rogers: The Yearly Variations in Plague in India in Relation to Climate: Forecasting Epidemics.—Dr. W. S. Patton and E. Hindle: The North Chinese Species of the Genus Phlebotomus.—H. Eltringham: On the Production of Silk by Species of the Genus Hilara, Meig. (Diptera), with an Appendix.—A. H. Hamm: On the Epigamic Behaviour of *Hilara Maura*, Fab., and two Allied Species.—Dr. H. M. Leake: Agricultural Value of Rainfall in the Tropics.

Royal Institution of Great Britain, at 5.15.—Prof. F. Ll. Griffith: Nubia in Antiquity and in the Middle Ages (1).

Institution of Mining and Metallurgy (at Geological Society), at 5.30.

Child-Study Society (at Royal Sanitary Institute), at 6.—Mrs. Stella Churchill: Sunlight in its Effect upon the Development and Growth of Children.

Institution of Electrical Engineers, at 6.—T. N. Riley and T. R. Scott: Insulating Oils for High-Voltage Cables.

Institution of Electrical Engineers (Irish Centre, Dublin) (at Trinity College, Dublin), at 7.45.—T. J. Monaghan: A Review of the Present Position of Wireless Telegraphy.

Chemical Society, at 8.—Prof. A. Fowler: Spectra and Atoms (Lecture).

FRIDAY, February 24.

Physical Society (at Imperial College of Science), at 5.—W. H. J. Childs: Some Methods of Estimating the Intensities of Spectral Lines.—Prof. P. W. Burbidge and N. S. Alexander: On Electrical Methods of Hygrometry.—L. Hartshorn: On Constants of Thermionic Valves.

Royal College of Surgeons of England, at 5.—W. D. Newcomb: The Relationship between Peptic Ulceration and Gastric Carcinoma.

Institution of Professional Civil Servants (at Central Hall, Westminster), at 5.30.—S. V. Goodall: Admiralty Floating Docks.

North-East Coast Institution of Engineers and Shipbuilders (in Mining Institute, Newcastle-upon-Tyne), at 6.—G. U. L. Sartoris and K. Watson: The Michell Crankless Engine.

Institution of Electrical Engineers (London Students' Section) (jointly with Students' Sections of Institutions of Civil and Mechanical Engineers) (at Institution of Electrical Engineers), at 6.15.—F. C. Dain: Salesmanship and its Application to Engineering.

Manchester Literary and Philosophical Society (Chemical Section), at 7.

Institution of Mechanical Engineers (Informal Meeting), at 7.—Exhibition of Industrial Kinematograph Films.

Junior Institution of Engineers (Informal Meeting), at 7.30.—C. H. Faris: The Applications of Electro-chemical Deposits of Metals to Engineering.

Royal Society of Medicine (Epidemiology Section), at 8.—Dr. R. Miller: Some Public Health Aspects of Juvenile Rheumatism.—Dr. J. T. Clarke: The Pathogenesis of Rheumatic Fever in its Climatological Relationship to a Possible Insect Carrier.

Oxford University Junior Scientific Club (in Department of Biochemistry and Physiology, Oxford), at 8.15.—Dr. A. E. Dunstan: Lecture.

Royal Society of Medicine (Diseases in Children and Surgery Sections), at 8.30.—Special Discussion on Chronic Appendicitis in Children. Dr. Robert Hutchison (Children); A. J. Walton (Surgery).

Royal Institution of Great Britain, at 9.—Prof. G. Gordon: The Lives of Authors.

Society of Chemical Industry (South Wales Section) (at Thomas' Café, Swansea).—N. H. Hartshorne: The Electronic Theory of Chemical Combination.

Chemical Industry Club.

SATURDAY, February 25.

North of England Institute of Mining and Mechanical Engineers (Associates and Students' Section) (at Neville Hall, Newcastle-upon-Tyne), at 3.—Dr. R. J. Perring: Miners' Nystagmus.

Royal Institution of Great Britain, at 3.—C. Dodgson: The Life and Work of Albrecht Durer (1).

PUBLIC LECTURES.

SATURDAY, February 18.

Horniman Museum (Forest Hill), at 3.30.—Miss M. A. Murray: Amulets and Magical Figures of the Ancient Egyptians.

MONDAY, February 20.

East Anglian Institute of Agriculture (Chelmsford), at 7.—A. Bridges: Sugar Beet Costs.

Gresham College, at 7.30.—G. P. Bailey: Modern Science and Daily Life: Chemistry in Industry.

Leeds University, at 8.—Dr. Ll. Wynn Jones: Recent Advances in Experimental Psychology: Analysis of Typical Results with special reference to Experiments on Cognition.

TUESDAY, February 21.

Gresham College, at 6.—A. R. Hinks: The Foundations of Astronomy (Succeeding Lectures on Feb. 22, 23, and 24.)

Theosophical World University Centre (153 Brompton Road, S.W.3), at 6.—Prof. E. Marcault: Principles of Race-Psychology. (Succeeding Lectures on Feb. 28, Mar. 6, 13, and 20.)

WEDNESDAY, February 22.

Royal Institute of Public Health, at 4.30.—Dr. J. H. W. Macfall: Some Aspects of Legal Live Birth.

THURSDAY, February 23.

British Medical Association (Tavistock Square, W.C.1), at 5.15.—Sir W. Heaton Hamer: Epidemiology in England during the last Hundred Years. Part 2. The Return to the Hippocratic Method (Chadwick Lecture).

Leeds University, at 8.—Dr. D. R. Fox: The Development of Public Education in the United States.

FRIDAY, February 24.

King's College, at 5.30.—C. J. Gadd: Ur in the Time of Abraham.

Theosophical World University (at Friends' House, Euston Road), at 5.30.—Prof. E. Marcault: Psychology of Man's Evolution. (Succeeding Lectures on Mar. 2, 9, and 16.)

East Anglian Institute of Agriculture (Chelmsford), at 7.—Dr. W. F. Bewley: The Cultivation of the Tomato.

SATURDAY, February 25.

Horniman Museum (Forest Hill), at 3.30.—Miss M. Edith Durham: Primitive Life in South-East Europe.

CONFERENCES.

February 21–24.

Carbonisation Conference (in Birmingham and Midland Institute and Queen's College, Birmingham).

Tuesday, February 21 (in Birmingham and Midland Institute).

At 10.30 A.M.—

W. J. A. Butterfield: The General Scope of the Gas Industry.

T. Hardie: Some Phases of Modern Practice in Gas Manufacture.

T. Hardie: Presidential Address to the Southern Association of Gas Engineers and Managers.

M. Barash and T. C. Finlayson: Continuous Vertical Retorts.

N. J. Bowater: Vertical Intermittent Chamber Ovens for Gas Manufacture.

R. H. Ruthven: Intermittent Vertical Chambers.

Wednesday, February 22 (in Birmingham and Midland Institute).

At 10 A.M.—

C. P. Finn and R. Ray: The General Scope of the Coke Oven Industry.

G. J. Greenfield and G. H. Harrison: Modern Coke Oven Practice.

E. C. Evans: Coke Research and the Steel Industry.

Thursday, February 23 (in Birmingham and Midland Institute).

At 2.30—

T. F. E. Rhead: Steaming in Vertical Retorts.

A. T. Green: Gas Works Refractories.

Dr. A. Parker: Gas Works Effluents.

Friday, February 24 (in Queen's College).

At 10 A.M.—

Sir Arthur Duckham: The Handling, Preparation, and Utilisation of Gas Works Coke.

J. Roberts: Blending in the Gas and Coke Oven Industries.

At 2.15—

F. S. Sinnatt: A General Review of Low Temperature Carbonisation.

February 24 and 25.

Association of Technical Institutions (Annual Meeting) (at Stationers' Hall).

Principal G. H. Austin: Commercial Education.

Principal S. Carter: Suitable Courses in Commerce for Small Institutions.

T. P. Bennett: The Technical Training of the Architect.

Principal F. E. Drury: Technical Education for the Building Trades.

F. W. Roberts: Technical Education for the Boot and Shoe Industry.

SATURDAY, FEBRUARY 25, 1928.

The Range of the Scientific Faculty.

> "How can we harness opinion to knowledge and steady the emotions of the multitude with experience and science? This, it seems to me, is the master problem of our time."
> J. A. SPENDER.

IN a recent address[1] on "Contacts of Science and Literature," which he delivered as president of the Science Masters' Association, Sir Richard Gregory has once more directed attention to the urgent need of a closer approach of letters and science. Sir Richard, as all know, is both broad and fair in his outlook; no one is less likely to present a prejudiced view of the situation; also he is ever an optimist. Any statement that he may make upon such a subject is not to be put lightly aside. In suggesting, as he does, that indifference to science among teachers of English is more general than neglect of literature by students of science, he is upon sure ground—almost that of platitude. What are we to say of his subsequent contention?

"We are not likely ourselves to forget that science and the humanities are the warp and woof of the fabric of modern life any more than we overlook the human factor in industry; but while these relationships are frequently presented to scientific assemblies, we miss the same friendly gestures to science from our literary colleagues. Men of letters tell us that men of science are the only people who have something to say and are unable to say it and we accept the rebuke, even though we know the difficulty of making the intricate processes of Nature intelligible in the vocabulary of ordinary life. Our retort, however, may very well be that men of letters should be expected in these days to know a little of Nature and science and to be able, therefore, to exercise their literary art in displaying the wonder and value of the rare treasures which the argosies of scientific explorers are continually bringing into our havens from uncharted seas. Science does not want a divorce from literature but closer union with it and a common understanding of the distinctive qualities by which each can contribute to the fullness of life. It would be easier to mention leaders of science who have enriched literature by their writings than to select men of letters who have exercised their imagination and art upon scientific knowledge and achievement; and we ask those who have the gift of radiant expression to remain no longer outside our temples but to enter and be moved to testify to the revelation which will then be given them."

Is the invitation thus given one that is likely to be accepted? Can men of letters ever enter into the Temple of Scientific Endeavour and do what is here asked of them? Have we not too long followed Adam and Eve?

> "Thus they in mutual accusation spent
> The fruitless hours but neither self-condemning
> And of their vain contest appeared no end."

---

[1] Published in the *School Science Review* for February.

Nothing can be gained by the one party always gibing at the other. Should we not rather consider the office of each, what is really within the power and province of each?

Man is to be distinguished from the rest of animate creation by three, if not four, faculties—that of speech, the use of hands, commercial ability and the use of fire. The art of scientific inquiry is but a modern discovery—a modern superstition, may we not say, something foreign to man's ordinary nature—superadded to it and necessarily the prerogative of the few? Carlyle has claimed that he is the tool-using animal, strangely forgetting that man, especially woman, is a literary creature almost from birth. The highest literary artist is but a biped in whom the chief art of his being is developed to the utmost—writing, after all, is nothing but the cultivated art of speech recording. It is no particular credit to us to write and speak well; rather are we to be blamed for the very partial and imperfect manner in which we are accustomed to develop and exercise our chief natural, inborn faculty.

Have we, then, not the right to rate the literary as an intellectually inferior class? Have they not mere ordinary brains, however highly developed? Hazlitt has painted them to the life, particularly in his essay "On the Ignorance of the Learned," in saying:

> "All that men really understand is confined to a very small compass: to their daily affairs and experience; to what they have an opportunity to know and motives to study or practise. The rest is affectation and imposture."

Can we expect the literary as a class, ever to be scientific? It is absurd to suppose that, if the power were latent in them, men of the seeming intelligence of say Oxford dons should be proof against all persuasion to take an interest in the work of scientific discovery and be unable to do more than use more or less ordinary words in dealing with the ordinary events of common life and continually to depict only the obvious—glory in being masters of inextensible subjects. In truth, there is a factor of intelligence missing from their minds—let us call it factor X.

Sir Richard rightly had much to say in praise of poetry—he quoted examples to show that the poet is able to seize upon and portray the findings of scientific observers, Tennyson's felicitous lines, in particular. Yet the poet of old, we have to remember, was but the singer, the speaker of music: he is only to-day the writer and put into print; he is but the highest form of speechmaker, no modern development or new discovery. Poetry, in fact, is more or less akin to our nature. Music also i a barbaric trait—it is in us all to some extent especially in Germans; there are few who do no hate noise, if they do not react to harmoniou sounds.

Again, no special claim can be made on behalf of commercial ability—it is necessarily more or les born in us all. From his earliest days, man ha been obliged to barter, buy and sell, in order to live at least, up to the time of the discovery of the dole the acceptance of which may but connote a superio form of commercial ability.

As to the use of fire, this is so ancient a custom that it is now an instinctive practice. Clearly it i not a sign of intelligence but rather the reverse—in its modern development, the sign of a desire for occupation and of its irrational satisfaction. The woman who knits, not only satisfies the desire of her being to be busy but also does something useful The smoker but deadens the same desire in destruction and dirt; it is true he occupies himself: the brute is tamed, usually *after* being fed—but wastefully and selfishly.

As to our use of hands, we could (we were allowed to) use these in the distant past to greater advantage than we do to-day: Egyptian tombs tell us this story. Only on Dec. 31 last, a picture was given in NATURE of a machine able to make a million bottles a week, which is to be worked by a single man Formerly, hundreds were needed to make any such number. None the less, *bottled* beer is dearer than it ever was. Who gains the advantage the hundreds formerly had from blowing bottles—what is behind the machine? Is it not the execrable modern discovery we call scientific activity? The effective activity of knowledge used systematically and by the very few, of set purpose, to a foreseen end?

The systematic use of scientific method, the method of using knowledge not merely to do this or that but also to extend and verify knowledge—through reasoned observation and experiment: the existence of men gifted with the factor X, this is the paramount discovery of modern times, scarce centuries old. Let this not be confused with mere science—which is but exact knowledge. The faculty of using knowledge is a rare one, almost a modern discovery. The scientific, therefore, may claim to be a superior people, a people who can advisedly, of set purpose, find things out and do things, whilst the literary can at most talk about them. Natural science, the work of this new class, may claim to stand alone as the music of the future: either its priesthood will be the leaders of the people—the givers and guardians of their necessary morality—or the people will perish, if not from want of knowledge, from lack of the power to use it.

The literary write themselves up everywhere—each goose as it comes to market is made into a swan in the reviews of to-day and the virtues in the classics are ever impressed upon us. Yet who shall say that the sciencers are behind: certainly not the physikers; the others at least write one another down. The scientific after all are much as other men, human in their foibles and vanities; yet they are gifted with a power—the mysterious factor X—which definitely divides them from the mass: however much they may be appreciated by society, they will never be really understood. In fact, they are very fine fellows and it is unfortunate that Mr. Bernard Shaw has not been induced to sketch their psychology for us—but they are a class of supermen which must ever be beyond such writers as he.

If our argument be sound, the literary will never do what Sir Richard Gregory suggests they should do. Factor X will never stir within them; they are mentally unresponsive. The work will only be within the power of those sciencers who are also competent as writers. As speaking is a common human attribute, there is no reason why such should not be forthcoming, provided the schools do their duty. These have yet to show that they can teach the use of words, let alone science. French men of science are able to write well, because training in rhetoric *is* given in their schools: in ours it is not.

To-day, the schools do not do their duty. They simply do not know what their duty is. They are controlled by people who only know the old knowledge and are without understanding of scientific method. Thring, the schoolmaster, told his colleagues long ago—to break down the knowledge idol. Sanderson, at Oundle, made an abortive attempt. Our universities are all engaged in its fervent worship. Education, like sport, is fallen a victim to professionalism: the system pursued is akin to that of the electric hare in coursing—its practical equivalent.

Being a nation of shopkeepers, willy nilly we are engaged in commercialising education in all its forms, including research. School is carried on mainly in the interests of the machine, not in the interest of scholars. Education is in the control of two of my inferior classes—the literary and the commercial. The writing upon the wall is very clear—needing no Daniel to interpret it. Who will read it out in the market places, so that it may be understood by all and my text be fulfilled? The first duty of scientific workers to-day is to the public. Having put such vast powers of exploitation in selfish hands, we at least must endeavour to inform the masses how best to use the opportunities before them—never to think of chalk as fuel.

To make university education of avail we must appoint teachers competent to teach, first the things of yesterday. Let the research workers be a class apart. The schools are not producing the men for whom the world is asking. We are moving to-day in a closed vicious circle—the schools say they are in the hands of the universities, whilst these retaliate that they are subject to the schools. Examinations pay everybody except the learner—the poor guinea-pig.

The teaching of science in our schools is a failure, because it is parrot work, not scientific; because it is confined to special subjects—chiefly chemistry and physics—geology, botany and biology being all but neglected; because it is so far beyond the common intelligence and the teacher's. No attempt is made in the schools to teach the simplest elements of scientific method, as applied to ordinary life and to ourselves. We must mend or end the system. The Science Masters' Association has neglected great opportunities in the past half-dozen years of discussing the problems, when at Oxford and Cambridge, with the authorities.

The public cannot allow the subject to be trifled with much longer; the two parties must meet and debate the situation, so that each may put its house in order without any further delay. H. E. A.

University College Centenary.

University of London: University College. Centenary Addresses. Bound together in one volume. With a Preface by Dr. R. W. Chambers. Pp. viii + 33 + 36 + 42 + 28 + 31 + 35 + 19 + 30 + 25 + 28 + 28 + 20. (London: University of London Press, Ltd., 1927.) 12*s.* 6*d.* net.

THE re-issue of these addresses in the form of a bound volume will be welcomed by an even wider public than the members and friends of University College, London. Anniversaries have been celebrated from the dawn of civilisation and correspond to something real and significant in human life. The 'majority'—the twenty-first anniversary—when a man comes to his estate and arrives at 'years of discretion,' was based presumably on some *pseudo*-physiological facts decocted by lawyers. It corresponds to nothing in the life of an institution, for an institution is born adult, at any rate in such matters as the privilege of paying income-tax. Jubilee, the year following the Jewish seven Sabbaths of years, when liberty was proclaimed and every man returned to his family, had originally a religious and racial meaning. A centenary, representing an arbitrary period of time based on our decimal notation, offers some advantages from the viewpoint of institutional celebration. In the course of Nature, the founders of a college are not privileged to be present at its centenary; and for that reason their memory and achievements may more appropriately be revived and revered. Further, a college which has survived for a century has passed the audits of time and can look forward with equanimity to its future.

There may be risks attending the foundation of new universities, said Mr. H. A. L. Fisher in his Foundation Oration reprinted in this volume, expressing the accustomed Oxford view on this question—risks which we venture to suggest are usually over-estimated—but those risks, he added, do not apply to an institution which has weathered one hundred years. In an eloquent tribute to the ideals for which University College was founded, he said:

> "Your college has given ample pledges. It has been served by a long line of distinguished teachers who have left their mark upon the intellectual life of the country. It has always stood for free and fearless inquiry. It has never receded from the large and undifferentiating hospitality which now, for one hundred years, it has extended to all who desire to learn."

Who was the founder of University College and of the University of London—for it is fair to acknowledge that the founder of University College was in one important sense the founder of the University? Thomas Campbell's letter to the *Times*, published in February 1825, urging the establishment of a great University of London, is well known. The letter was addressed to his dear friend Brougham, a somewhat sinister figure in the political life of his times, a man who was not a hero even to his biographer. Aspinall, in his book "Lord Brougham and the Whig Party," animadverts on his "faithlessness and egoism"—characteristics not to be looked for in a pious founder—but he pays tribute to the "influence, energy, and capacity" which "did most" to carry Campbell's scheme to execution. To Brougham, therefore, honour is rightly accorded in this centenary volume. But the authorities of the College have shown a wise discrimination in selecting Jeremy Bentham for special praise and thanksgiving as a founder of the College.

"I do not suppose," said the Bishop of Manchester, in the sermon preached at the special service in Westminster Abbey, "that it would be extravagant to say that no man in English history has accomplished so much definite good that can be plainly traced to his work and influence as Jeremy Bentham": and this high praise is endorsed by Prof. J. E. G. de Montmorency in his notable address on "A Century of Jurisprudence," who accords to Bentham the proud title of spiritual founder of University College "a utilitarian if you like, but a utilitarian who, being dead, has slowly brought the Platonic heaven to earth."

From the founders of University College we may pass to its teachers and students. Once a year the members of the College come together "to pay a tribute to the memory of our founders and to some of the distinguished men and women who have done so much to make the name of this College famous." Two of these commemorations are recorded in this volume, the first, on March 25, 1926, when the Provost (Sir Gregory Foster) delivered the Foundation Oration, and the second, a year later, when the delegates from 208 universities and colleges assembled to honour the centenary of the College, the orator on this occasion being Mr. H. A. L. Fisher, to whose address reference has already been made. Two lists of names selected for special honour are therefore published in the book. We do not claim to discern the principles on which the names are selected, for if the lists include some distinguished names, others not less distinguished are excluded—de Morgan, Lister, and Walter Bagehot, for example. Lister, one of the greatest benefactors of the human race, was a true son of the College, graduating both in arts and medicine, and receiving later in his life the rare distinction of an honorary degree from the University. Walter Bagehot, described by Morley as a "striking genius," had a deep and pervasive influence on political and economic thought, an influence not dissipated by the catastrophic events of recent years. He was elected a fellow of the College in 1849, and was induced to offer himself as a candidate for the original representation of the University of London in Parliament. Surely also, among former professors, Augustus de Morgan, the brilliant mathematician, should be considered worthy of inclusion among the teachers who built up the fame of the College; and might not the name of a representative of those students who fell in the War—William Howard Lister, for example—have been included in one of the lists, or even in both lists, to which are appended the memorable words:

"All these were honoured in their generations, and were a glory in their days. Their glory shall not be blotted out."

The only name accorded the honour of inclusion in both lists is that of a benefactor, Sir William Bartlett, Bart.

Sir Gregory Foster selected an avowedly historical subject for his Foundation Oration—"These Hundred Years." This was, as to date of delivery, the first of the addresses included in this volume, and might well have been placed at the beginning of the book as furnishing an introduction to the other addresses. The address is full of interest to the student of educational history. If there is one subject for criticism, it is that the question of the relation of the College to the University of London might have been examined in more detail and with greater care. Reference is made to the 'evil' results to the London Colleges of "the severance in 1858 of the University from the affiliated Colleges." The word 'severance' is inappropriate to describe what took place at this time. Affiliation of colleges had become in course of time practically meaningless, and the affiliation of further colleges was therefore discontinued, the examinations (except in medicine) being thrown open to all comers. The relation of University College to the University remained, however, much as before. According to official evidence presented to one of the numerous Royal Commissions which have investigated the university question in London, both the University and University College received their original charters on the same day in 1836, and the College was always tacitly regarded as the teaching department of the University.

The union, it is true, was not organic; and the word 'severance' cannot therefore be used either as implying the pre-1858 relation or as defining the post-1858 relation of College to University. "Reform came in 1900," we are told, "but that reform was a tentative step." A tentative step, forsooth! The drab old gentleman of Burlington Gardens, busy exclusively with his written and practical examinations, was metamorphosed by this reform into an Apollo to whom the College at once proposed matrimony—'incorporation' is the technical word—a complete fusion of interests! "As you know," the Provost continued, "only the day before yesterday, a new plan of 'evolutionary' development was issued by the Departmental Committee appointed by Mr. Trevelyan." Is this a worthy reference to the culmination of twenty-six years of anxious thought and discussion, in which the Provost's views have always been listened to with strained and respectful attention? Great praise is accorded by the Provost to the "Education Acts of 1901 and 1902"—the reference must be to the Acts of 1902 and 1903—and to their inspirer, Sir Robert Morant. "Owing to those great Acts, the growth in this College and in other university institutions throughout the country has been remarkable." Has the College, the wayfaring man will ask, gained nothing from the closer association with the University and the other London Colleges secured by the "tentative" reform of 1900? By a slight extension of the title of his address, the Provost might well have attempted to limn the vision of the new University of London, with its libraries, research institutes, and special schools, growing in beauty and harmony alongside its greatest college—

"Yet ever and anon a trumpet sounds
From the hid battlements of Eternity;
Those shaken mists a space unsettle, then
Round the half-glimpsèd turrets slowly wash again."

Interesting as the history of the College undoubtedly is *per se* and in relation to the development of our educational system, the addresses here reprinted on the progress of science during the century will appeal more directly to scientific readers—physiology by the late Prof. E. H. Starling, physics by Sir Oliver Lodge, a brilliant and characteristic *causerie*, medicine by Sir John Rose Bradford, electrical engineering by Prof. J. A. Fleming, and chemistry by Prof. J. Norman Collie. "At the date of the foundation of this College," said Prof. Starling, "science as an academic study was practically non-existent in this country." The College suffered abuse in its early days not only for its 'godless' character, but also on account of its enthusiasm for scientific teaching and research. 'Stinkomalee' was one of the epithets specially coined for the purpose of this abuse; and the noble motto *Patens omnibus Scientia* was converted into a nickname—Brougham's Patent Omnibus. An abridged list of names will suffice to establish the claims of the College in this respect. In physiology, the College can point to Sharpey and to his brilliant pupils Burdon-Sanderson, Michael Foster, and Schafer, of whom the first two bore the torch to Oxford and Cambridge; to Bayliss, Horsley, and Starling. In physics and chemistry, the list is not less distinguished, including the names of Graham, Williamson, and Ramsay. And may we not add that many of those who are still living and working in the College are worthily maintaining the high tradition of scientific research set by these honoured names?

"It is one of the glories of University College," said Mr. Fisher, "that it has contributed not to education only, but to the advancement of learning, and that its alumni and professors are taking their full share in that great movement of human curiosity, which is transforming our conceptions of the physical constitution of the universe, as well as in the many laboratory experiments which in the last one hundred years have lessened the physical sufferings of mankind." T. LL. H.

The Oldest of the Arts and the Youngest of the Sciences.

Animal Ecology: with especial reference to Insects. By Royal N. Chapman. Second edition. Pp. ix + 187 + 183. (Minneapolis, Minn.: Burgess-Roseberry Co., 1927.) n.p.

PRESIDENT LOWELL was assuredly wrong when he gave to *business* the title of "the oldest of the arts and the youngest of the sciences." The art by which, for example, the naked Australian black extracts the means to live from country where a white man would starve—this art of food-getting—is surely older still. It depends on an extraordinarily detailed empirical knowledge of the habits, inter-relations, and distribution of animals and plants; in other words, on the subject matter of that newest of the sciences which clamours for the attention of every thinker under names as varied as the philosophic outlook of its numerous exponents.

Prof. W. M. Wheeler, so long ago as 1902 (*Science*, N.S., vol. 15, pp. 971-976), exposed the abundant synonymy to which its wide appeal has led. The first attempts to codify this knowedge took the form of such natural histories as that of Pliny. From this general, diffuse, and impractical subject split off specialised fragments like taxonomy and its ungrateful children, morphology and physiology. By these were organisms more or less satisfactorily named, their parts and the functions of those parts described. There remained that which was the *fons et origo* of man's primitive interest in animals and plants—their relations with other organisms including himself—in other words, what they do. This residual biological science was first distinguished by Saint-Hilaire in 1859 as *ethology*—a term which we may agree with Wheeler is etymologically more appropriate and all-embracing than any of its proposed successors. These latter were Haeckel's *Oekologie* (1866) (English *œcology* or *ecology*), Ray Lankester's (1889) *bionomics*, and Whitman's, Lloyd Morgan's, and Watson's *behaviour*, to which may be added the French *comportement* and the restricted German *Biologie*.

In man's dealings with organic Nature, the life and death practical necessities of this knowledge have been hitherto met almost solely by crudely empirical or traditional means. His conquest of the inorganic world by the application of the more exact physical sciences has now brought him to the position that he must either bring increasingly the biological sciences into his relations with other organisms, or lose that civilisation which physics and chemistry have built up but cannot unaided maintain. This is essentially a matter for applied ethology. Whatever else his specialised studies have made him—agriculturist, medical man, entomologist—the grower of man's crops and his and their protector against diseases and pests must be in increasing measure an ethologist.

So long ago as 1784, Bernardin de Saint-Pierre, whose ethological viewpoint is strikingly modern, envisaged that application of the qualitative data of entomological ethology now exciting considerable and well-deserved interest in the principle of biological control, or the suppression of insect pests by means of their natural enemies. He writes:

> "It is important for us to be acquainted with at least such insects as destroy those offensive to man. We might take advantage of their hostility, and convert it into the means of our own repose. The spider catches flies by a net; the ant-lion surprises ants in a tunnel of sand; and the four-winged ichneumon seizes butterflies on the wing. There is another ichneumon so small and so cunning that it lays an egg in the anus of the vine-fretter. Man has it in his power to multiply, at pleasure, the families of insects which are useful to him, and he may find the means of diminishing such as commit depredations on his agricultural possessions."

In spite of the fact that the qualitative data on insect ethology are now extraordinarily voluminous—and commensurately difficult to codify and to synthesise—they are still fundamentally and appallingly incomplete. There is probably not a single injurious insect which could be at present economically controlled on the basis of data already accumulated and without the acquirement of further merely qualitative information. We therefore regret to see that Dr. Chapman, in the work under review, scorns *qualitative* data. He has, however, performed a service of inestimable value in bringing together references to or examples of almost all the *quantitative* work which has been accomplished on the ecology of insects. He has produced a book which Oliver Wendell Holmes' specialist in the Scarabæidæ might well have regarded with dismay, but it undoubtedly indicates the type of knowledge which must form part of the equipment of the applied entomologist of the future.

The entomologist of the old school was—and is—too prone to regard the place and time of capture and the movements of the insect in view, as more or less accidental; or if the latter looked purposeful or intelligent, to ascribe them to the workings of an inscrutable 'instinct' which stood like a wall against further inquiry. This reproach applies as much to the morphologist as to the taxonomist. The specificity of insect behaviour is so great that taxonomy must inevitably form the foundation of all entomological research and the basis of all intelligent ethological work; but the economic entomologist should above all remember that it is what the insect *does* which matters. Dr. Chapman has assembled a vast amount of useful data to show what it tends to *do* under the influence of all those extremely numerous stimuli which are exerted by the inorganic and the organic environment.

It is only fair to suppose that when this mimeographed book is finally printed such slips as "voluminious," "vestigal," "stimulæ," "calabrate," "resperation," and "canabilistic" will disappear. It may also be noticed that the leafhopper which threatened the Hawaiian cane-fields was not *Pyrilla aberrans* but *Perkinsiella saccharicida* Kirk., a very different insect. J. G. Myers.

Early Man in East Anglia.

The Antiquity of Man in East Anglia. By J. Reid Moir. Pp. xiv + 172 + 25 plates. (Cambridge: At the University Press, 1927.) 12*s.* net.

MR. REID MOIR'S researches into the evidence for the antiquity of man in East Anglia have excited such widespread interest that he has done good service by summarising the results in a single convenient volume. He has provided for the specialist by giving copious references to the original papers by himself and others, in which the facts and observations were first published. He has also attempted to interest the general reader by enlivening his narrative with some popular interludes and elementary explanations. His numerous beautiful drawings and photographs add greatly to the attractiveness of the book.

Most of the work naturally deals with the Eolithic and Palæolithic divisions of the Stone Age, with which Mr. Reid Moir has been specially occupied. The evidence is chiefly that of flint implements, and as he admits that "it is very difficult, if not impossible, to tell in every case if any single flaked flint of a primitive, simple type is the result of human intention or natural fracturing, such as is caused by pressure or percussion," he begins by explaining the criteria on which he relies. He is satisfied that the 'eoliths' first found by the late Mr. Benjamin Harrison on the North Downs are "the earliest flint implements known to science, which were made by a race of ape-like people living in Kent, perhaps a million years ago." His explanation of the Eolithic plateau in Kent, however, is marred by a crude diagrammatic section across the Weald, which represents strange unconformities that do not exist. He considers that the occurrence of similar 'eoliths' in the detritus bed below the Red Crag in Suffolk fixes the geological age of this plateau, which he regards as early Pleistocene rather than late Pliocene. Both the Red and Norwich Crags are referred to the Pleistocene. All the 'eoliths,' however, are rolled and waterworn, and thus belong to an earlier period than the deposits in which they occur.

The large 'rostro-carinate' flint implements which Mr. Reid Moir was the first to recognise at the base of the Crag, are regarded as being of later date than the 'eoliths' and as forming "a connecting link between these primitive artifacts and the later palæoliths." He gives good figures of 'rostro-carinates' and various other chipped flints found associated with them, and thinks that some of the pieces of fossilised bone of the same age show traces of shaping by man.

Several early Palæolithic flint implements of the Chellean type, including one large specimen weighing 7 lb., are described as obtained from the Cromer Forest Bed. A fragment of wood, apparently yew, and a piece of fossilised bone, are supposed to have been shaped by man; and three bones discovered by Mr. A. C. Savin in the upper part of the Forest Bed at West Runton, are said to show "clearly defined cuts" which "can only have been produced by flint knives in removing the flesh."

Numerous Acheulean and later Palæolithic implements are known from several localities, of which interesting descriptions and illustrations are given. In some cases there are associated remains which afford scope for speculation. On one of the upper Palæolithic floors at Ipswich, fragments of human bones "exhibit cuts and marks of scraping and gnawing," from which it is "evident that the occupants indulged occasionally in cannibalism." On the same level were found some planks of wood and stakes, which are supposed to have been part of a wind-screen like that still constructed by the primitive Australians. Among surface finds which have also been regarded as probably of Palæolithic age, may be specially mentioned the natural cast of a chamber of ammonite from the chalk, which Mr. Reid Moir still thinks has been touched up by man to give it the semblance of a mammoth.

To complete his account of the Old Stone Age, Mr. Reid Moir adds a short chapter on the known human remains from other localities, and concludes with some reference to East Anglian discoveries. It is difficult to believe that the very modern type of human lower jaw from Foxhall dates back to the period of the Red Crag in which it was found. The claims of the so-called Ipswich man to Palæolithic antiquity are also somewhat doubtful.

One chapter is devoted to the Neolithic period in East Anglia, with beautiful illustrations especially of the discoveries at Grime's Graves. Mr. Reid Moir suggests that these flint mines may have been begun in Palæolithic times, and includes a good photograph of the flint incised with the outline of an elk, which was discovered by Mr. Leslie Armstrong.

The men of the Bronze Age and later times in East Anglia are known chiefly from remains in burial mounds and cemeteries. There are still flint implements in some of the mounds of the Bronze Age, and a flint implement was found in each hand of a skeleton in one of the Roman cemeteries. In the latter case the implements were well patinated and clearly much older than the Roman period.

In a concluding chapter, Mr. Reid Moir discusses the place of origin and the progress of man. He thinks that England is just as likely as central Asia to have been his original home, and he pleads for a more intensive examination of the later geological deposits in Britain. He himself has long pursued the research with indefatigable zeal and with " well ordered imagination " (as he terms it), and his new book should stimulate others to follow his example. A. S. W.

Our Bookshelf.

A Graphic Table combining Logarithms and Anti-Logarithms : giving directly without Interpolation the Logarithms to Five Places of all Five-place Numbers and the Numbers to Five Places corresponding to all Five-place Logarithms ; also a Graphic Table as above reading to Four Places. By Adrien Lacroix and Charles L. Ragot. Pp. xi + 46. (New York : The Macmillan Co., 1926.) 6*s*.

THIS volume presents a 5-figure logarithmic and a 5-figure anti-logarithmic table in graphical form. A typical page is that providing the logarithms of the numbers 40,000 to 43,000. Twenty-five horizontal lines are divided on their upper side into 3000 parts, each about one mm. lomg. Every tenth division is numbered, thus forming a linear scale from 40,000 to 43,000. The lower side of each line is graduated logarithmically, these graduations extending from 0·60206 to 0·63347. Hence the logarithm of a number may be found to five decimals without interpolation by locating the point in the upper scale corresponding to the number, and then reading the lower scale at this point. The reverse process serves for the finding of a number from a given logarithm.

Although suggestive of the slide rule, the graphical table is merely one of logarithms and anti-logarithms. The advantages claimed are the elimination of interpolation, and compactness, for the table occupies only 40 pages as against 380 for a fully printed 5-figure table. The authors do not seem to be aware that such a table actually exists in Scott's " Tables of Logarithms and Anti-Logarithms to Five Places," which, incidentally, is sold at exactly the same price as their table. The choice between the two tables is entirely a matter of temperament. One computer will find the graphical table easy to use, while another will find the reading of scales irksome, as it calls into play faculties which he does not usually exercise in his profession, and so will prefer the extra labour of turning over more pages, with its compensation of the fully printed result opposite a fully printed argument.

At the end of the volume is a similar 6-page graphical table giving directly 4-figure logarithms and anti-logarithms, which would meet the needs of most workers in engineering, the field in which graphical methods are most in vogue. L. J. C.

Memoirs of the Geological Survey, Scotland. The Oil-Shales of the Lothians. Third edition. Part 1: *The Geology of the Oil Shales Fields.* By R. G. Carruthers, based on the work of H. M. Cadell and J. S. Grant Wilson. Part 2 : *Methods of Working the Oil-Shales.* By H. Caldwell. Part 3 : *Chemistry and Technology of the Oil-Shales.* By E. M. Bailey. Part 4 : *History of the Scottish Oil-Shale Industry.* By H. R. J. Conacher. Pp. x + 274 + 12 plates. (Edinburgh and London : His Majesty's Stationery Office ; Southampton : Ordnance Survey Office.) 5*s*. 6*d*. net.

THIS memoir was first published in 1906, revised in 1912, and is now in its third edition. It deals fundamentally with the geology and technology of the Scottish oil-shales, and now, as hitherto, constitutes the standard authority on the subject, especially concerning Scottish retorting practice. Much of the section on the chemistry and technology of the shales has been rewritten by Mr. E. M. Bailey, while the methods of working the raw material have been revised by Mr. W. Caldwell. An interesting part has been added by Mr. H. R. J. Conacher on the history of the industry since its beginning in 1858 up to the present day. In other respects the volume is not greatly changed, except for the addition of several excellent illustrations and a decidedly improved version of the geological map. A sheet of comparative vertical sections depicting stratal sequences in different areas is included and helps considerably in the visualisation of underground conditions. Considering the size and comprehensive nature of this volume, the price is remarkably modest, and a wide circulation should ensue.

Ethnographical Studies in Celebes. By Dr. Walter Kaudern. Results of the Author's Expedition to Celebes, 1917–1920. Vol. 3: ***Musical Instruments in Celebes.*** Pp. xiii + 322. (The Hague: Martinus Nijhoff, 1927.) 20*s.* net.

THE third instalment of Dr. Kaudern's reports on his ethnographical expedition to Celebes in 1917–1920 deals with the musical instruments of the island as a whole, although the original intention was to deal with those of the Toradja. As so frequently happens, however, he found that the study of distribution of the instruments used by these tribes only lacked completeness without a study of all the groups. His own collection of instruments was large—the list given here runs to several pages—but it was in itself insufficient for his purpose. In drawing upon the material in several museums, the data of provenance, etc., were at times inadequate, and to this extent, as he himself confesses, from the absence of his own personal observation, there is necessarily sometimes a lack of precision in the information available.

The musical instruments are classified according to construction into idiophones, some of which are not truly instruments at all, being merely devices for producing a rattling sound devoid of rhythm, membranophones, cordophones, and ausphones. Several of the instruments have been introduced from outside; the bamboo flute of the schoolboy band mentioned by the author, for example, is of the common transverse form, which is not a native type. At one time there was a rule that certain instruments could be played only by certain people at certain times, but this has now died out. Dr. Kaudern's valuable study of a little known subject is very fully illustrated—a matter of the greatest importance in any work on musical instruments.

Mathematical Geography. By Prof. A. H. Jameson and Prof. M. T. M. Ormsby. Vol. 1: ***Elementary Surveying and Map Projection.*** Pp. ix + 154. (London: Sir Isaac Pitman and Sons, Ltd., 1927.) 5*s.* net.

ALTHOUGH the subjects of field-work, surveying, and map projections are intimately associated, books have been devoted previously to one or two of these sections only. The study of map projections has aroused considerable interest recently, and now we are given a book which covers the whole of this work in broad outline.

The book is in two portions, which relate respectively to surveying and projections. In the former part, the three methods, chain, plane-table, and compass, together with relevant matters, are treated with clearness. One noteworthy feature which strikes the reader is the detailed description of the apparatus and of the method of its use. In the second part the small space is utilised fully. Although all the cases, equatorial, polar, and oblique, of the projections could not be treated separately, the commonly used projections are described, their uses are considered with examples, and the student is introduced to their constructions.

The authors have wisely, though perhaps a trifle harshly, warned students against imagining projections by means of a spot of light (p. 99). Thus errors due to facile conceptions will be avoided.

The work will be welcomed by geographers for its scope and clarity, and, moreover, with the exercises appended, will prove useful to all who are interested or concerned with this subject.

J. ELING COLECLOUGH.

Problems in Psychopathology. By Dr. T. W. Mitchell. (International Library of Psychology, Philosophy, and Scientific Method.) Pp. v + 190. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., Inc., 1927.) 9*s.* net.

THE editor of the *British Journal of Medical Psychology* is a whole-hearted Freudian and does Freud justice. He shows how the study of hypnotism and hysteria in the late nineteenth century resulted in the development by Freud of his theory of psycho-analysis. He discusses very clearly the theory of the libido and Freud's conception of the Ego, the Super Ego, and the Id. Freud's views on the instincts are of course more or less unique, and the author, although critical, treats him fairly. In the chapter on the neuroses, he presents us with Freud's view that the repressed libido finds outlet through condensation and displacement, distortion, and disguise in neurotic symptoms. In his concluding chapter he points out in no uncertain manner that neither Jung nor Adler can be in any way considered as psychoanalysts. When Dr. Mitchell writes anything we expect a brilliant effort, and we are not disappointed in this series of lectures.

American Game Shooting. By Capt. Paul A. Curtis. Pp. xvi + 279 + 15 plates. (New York: E. P. Dutton and Co., 1927.) n.p.

CAPTAIN CURTIS writes with twenty years' experience of game shooting in the United States and Canada. He admits that he is not a naturalist, but all the same he has studied closely the habits of various animals. Many naturalists might read his chapters with interest if every study of the ways of the animals were not an introduction to the best means of killing it. He deplores the decrease in wild life in America, and believes that big-game hunting in the United States is practically over; he estimates that, outside zoological gardens and the Yellowstone Park, there are only 250 grizzly bears in the United States. The author disparages indiscriminate slaughter, but the destruction of the game is surely in some measure due to the sport of hunting, of which he is so keen an advocate. He cannot expect every hunter to be so careful as he is not to overdo the sport. His own enthusiasm must contribute to the end which he deplores.

Letters to the Editor.

Liquid Stars.

IN NATURE of Feb. 4 (p. 173), Dr. Jeans has given an attractive exposition of his new theory of stellar evolution involving 'liquid' stars. With all goodwill towards innovations which might help to remove present difficulties of the evolutionary theory, I cannot follow Dr. Jeans's lead because I find myself in disagreement with him on two preliminary and essential points. These points, discussed separately below, have already been the subject of careful investigation, and even in Dr. Jeans's fuller papers on his theory I find no new considerations which would modify the conclusions formed.

(1) STATE OF HIGHLY IONISED MATERIAL.—The theory put forward in 1924 that stellar material is a nearly perfect gas up to densities exceeding those of terrestrial solids met with surprisingly little opposition at the time; but opposition has now come in the form of Jeans's liquid stars. Fortunately, he and I are agreed as to the extent of the ionisation. In the upper half of the main series the ions are chiefly nuclei attended by two K electrons—a structure having a radius of about 10^{-10} cm. The average distance between neighbouring ions is at least 100 times greater. Jeans assumes heavier ions than I do, but that only augments the disparity between size and separation. The hypothesis of liquid stars postulates that in this condition the ions are jammed; that is to say, their effective volumes are 100.000 times greater than the volume covered by the electron system, and the space apparently so empty is in reality packed full The defence is (*Mon. Not. R.A.S.*, **88**, p. 736): "Even with neutral helium the effective diameter of the atoms in the liquid state is 7·4 times that of the electron orbits as calculated from Bohr's theory. No one can say what it would be if the temperature were raised from two or three degrees absolute to ten or a hundred million degrees absolute, and we might, in any case, expect atoms surrounded by a powerful electric field to have relatively larger effective diameters than neutral atoms such as that of helium." The last defence is certainly wrong. The effect of the electric fields has been investigated by Debye and Hückel, Kramers, and (with more specific reference to stellar conditions) by Rosseland, Fowler, and myself. It is not necessary to read far into these investigations to see that the electric fields make the gas superperfect and have the opposite effect to that which Jeans expects. His first defence is an *ad hoc* postulate that at high temperatures something unknown to present-day physics intervenes to give the ions what is apparently an impossibly large volume. All the evidence is that the volume diminishes with increasing temperature. Moreover, I understand that atomic volume is now generally regarded as conditioned by Pauli's exclusion principle, and I cannot think that physicists will easily be persuaded to admit the enormously extended sphere of exclusion demanded by Jeans.

Dr. Jeans's reference to atomic volume is so brief and perfunctory that I think I am not misrepresenting him in saying that he adopts liquid stars, not on grounds of physical plausibility, but for reasons somewhat as follows. He has persuaded himself that a gaseous star is necessarily unstable. Therefore a star in any one of the long-enduring stages *cannot* be gaseous; and if present-day atomic physics declares it to be gaseous, then so much the worse the present-day atomic physics. This is logical enough if we grant his premises—which I do not.

(2) THERMODYNAMIC INSTABILITY.—Any inclination I may have had to discuss Dr. Jeans's earlier theories of evolution was arrested at the start by disagreement as to stability; he made out to be stable the stars which I (following Russell) found unstable, and vice versa. He has now come into line with Russell and myself in agreeing that if the rate of liberation of subatomic energy E decreases as a consequence of compression the star is unstable. In the other direction agreement is still not complete. I have maintained that if E increases moderately with compression the star is stable, but too rapid a rate of increase will throw it into pulsation. Jeans does not disagree with this for the smaller stars, but he claims to have shown that for stars of mass greater than 2 × sun the range of stability disappears. The cause of this divergence is pointed out by H. Vogt in the current issue of the *Astronomische Nachrichten* (No. 5545), who shows that Jeans has omitted a term in his equations, and when the term is included the range of stability does not disappear. The range of stability is, however, rather narrow, and I have long urged the consequent difficulties (NATURE, Mar. 21, 1925; May 1, 1926) which seemed to be passed over too lightly in Jeans's earlier theories of stellar evolution. I have pointed out that the range is widened indefinitely if the liberation of energy is a two-stage process with a time-lag between the formation of the active substances and their spontaneous disintegration. At present this seems the most plausible way out of the difficulty. In any case it scarcely calls for the desperate remedy of liquid stars.

With regard to the evolutionary part of his theory, I am puzzled to find these 'liquid' stars behaving very differently from the way we supposed them to do when last I (like others) believed in them five years ago. Then the effect of loss of energy and contraction was that the liquid core increased in size and diminished in temperature. This still seems to be the correct deduction. But it would rule out the increase of central temperature, with consequent jumps to states of higher ionisation, on which Jeans relies.

In refusing to follow Jeans into the fire, I do not wish to give the impression that the situation is entirely comfortable in the frying-pan. Besides numerous difficulties associated with sub-atomic energy, there is the discrepancy of a factor 10 or more which I found between the stellar absorption coefficient and the value derivable from Kramers' theory of electron capture. Although Jeans alludes to this as one of the difficulties of the gas theory, I am not sure from his discussion whether the liquidity of the stars is supposed to cure it or whether he adheres to his former view that the discrepancy is removed by assuming very heavy elements in the stellar interior. The latter possibility was examined when the discordance was discovered, and it appeared that there was little or no advantage in substituting heavy elements (*Monthly Notices*, **84**, p. 110; "The Internal Constitution of the Stars," § 168). If, on the other hand, he explains the discrepancy by liquidity, so that the perfect gas curves for giants run $2\frac{1}{2}$ magnitudes above those shown in his diagram, I can only feel the more amazed at the prodigous size of his ions which in M type stars must be supposed to jam at densities $\frac{1}{10}$ that of air.

A. S. EDDINGTON.

Observatory, Cambridge,
Feb. 12.

I AM very glad to have seen Prof. Eddington's critical comments on the theory of liquid stars.

The difficulty as to atomic diameters, which he places in the forefront, and also in the tail, of his letter, seems to me also to be the most serious difficulty in the way of the theory. But Prof. Eddington overestimates its amount, though arguing as though I maintained that the stars were liquid throughout, from centre to surface. If a star such as Betelgeuse breaks up by fission, it probably forms a binary system with the dimensions of V Puppis. If so, considerations of angular momentum show that before fission the greater part of its mass must have resided within about a twentieth part of its radius from the centre. For this reason I imagine Betelgeuse to consist of a liquid core having a radius perhaps only five per cent. of that of the star, while the other 95 per cent. of the radius is occupied by very tenuous gas. The small core determines the dynamical behaviour of the star, because it contains most of the mass; the rest is a mere obscuring veil. In more ordinary stars the liquid core may extend over perhaps a third or a fifth of the radius.

This consideration reduces the diameters which Eddington assigns to my ions by a factor of from 3 to 20, and the ionic volumes by a factor of from 27 to 8000; for example, the concluding words of his letter should not be "densities $\frac{1}{100}$ that of air," but "densities 80 times that of air," which makes a difference.

All the same, the hypothesis admittedly requires effective diameters many times larger than the orbital diameters of the Bohr atom. What Eddington describes as my "defence" of this was only meant as a suggestion. It may be wrong, but I am surprised at Eddington describing it as "certainly wrong"; it had never occurred to me that modern quantum-dynamics was quite so sure of itself as this, especially in dealing with states of matter of which we have no experience. Meanwhile the atom, like the stars, is dissolving into radiation, and the wave-mechanics may throw new light on the matter before long. But I frankly admit the difficulty as a bit perplexing, although not in the least as fatal or insuperable.

I cannot follow either Eddington's arguments or his statements about instability, and I have not yet studied Vogt's paper in detail. I ought, however, to say that my own mathematical analysis did not confirm Eddington's conjecture as to the efficacy of a time-lag in promoting stability. With a long enough time-lag all matter is obviously reduced to the purely radioactive condition in which the liberation of energy is uninfluenced by changes of temperature and density, and I think Eddington agrees with me that gaseous stars of this type are unstable all along the line and in every conceivable configuration in which the gas laws are obeyed. I would also remark that, even if I were to concede all of Eddington's statements and arguments, the validity of the theory of liquid stars would remain absolutely untouched; his arguments are not directed against the tenability or accuracy of the theory, but only against its inevitability.

On this question, may I point out that there are only two possibilities open—in the central regions of stars, either the gas laws are obeyed or they are not. The former is the hypothesis of gaseous stars, and the latter of liquid stars. I still consider that stability considerations rule out the former, and so make the latter inevitable. But, apart from this, the theories admit of almost direct observational test, by comparing their predictions with the observed Russell diagram, which is observationally indisputable.

For the configurations possible for stars of given mass. the theory of gaseous stars predicts a system of parallel, slant, approximately straight lines. The theory of liquid stars predicts the wavy curves I showed in my article in NATURE. Seares (*Astrophys. Jour.*, 55, p. 195; 1922) has drawn the lines indicated by observation and gives a set of curves which are very wavy indeed, and show the same general characteristics as the curves requisite for liquid stars; they show no resemblance at all to the straight lines of gaseous theory.

The two opposing theories can also be tested in terms of the areas of the Russell diagram which are tenanted by stars. The theory of liquid stars predicts a diagram shaped like a hand with white dwarfs lying along the thumb. Observation shows a diagram shaped like a hand, with white dwarfs lying along the thumb, the only complication being that observation cannot reach down to where the thumb joins the hand. The theory of gaseous stars predicts merely a flat, featureless diagram, into which features can only be introduced by extraneous *ad hoc* assumptions. Yet the observed features of the Russell diagram represent the outstanding facts of physical astronomy. Consider, for example, the almost sensational fact that no star of solar mass is known with a density intermediate between 1·4 (the sun) and 50,000 (Sirius B). The atomic nuclei are 15 times as widely spaced in one star as the other, and no intermediate spacing is known to astronomy. What does it mean? Apart from liquid stars, I know of only one suggested explanation, and this is purely *ad hoc*. All stability considerations being thrown to the winds, the stars are supposed to radiate by the same mechanism as an explosive at its flash-point. The flash-points of the sun and Sirius B are supposed to be so different that one is reached at a density of 1·4, and the other only at a density of 50,000; and it is assumed that no type of stellar matter exists with a flash-point intermediate between these two extremes. Does Prof. Eddington really prefer to accept this medley of *ad hoc* assumptions rather than concede the effective diameters demanded by the theory of liquid stars? Of course, he may say he prefers neither, thereby laying himself open to the charge he brings against me of waiting for something unknown to present-day physics to turn up.

I obviously cannot occupy more space, but I think all the other points raised by Prof. Eddington are dealt with in my papers in the *Monthly Notices*.

J. H. JEANS.

The Nature and Function of Golgi Bodies.

As he attributes to me the fallacy "that things which look alike are necessarily the same," it would appear that Dr. Ludford had forgotten parts of my letter to NATURE, Jan. 21, and corresponding parts of my paper (*Proc. Roy. Soc.*, B, vol. 101, 1927), before he wrote (NATURE, Feb. 4). These parts are very important, and show that, whether right or wrong, my arguments are not based upon the fallacy that Dr. Ludford sets up, and then proceeds to knock down.

All cells contain lipins. If acetic acid is used in fixing fresh material, the appearances known as 'Golgi bodies' are absent. If no acetic acid is used in the fixative, they appear after suitable treatment. My mixtures containing lipins behave in exactly the same way. The Golgi bodies appear or are absent, under the same conditions as they appear or are absent, in fixed cells.

If the Golgi bodies are really cell structures and not the products of the treatment to which the cells are subjected, then there should be two sets of Golgi bodies in each cell, for lipins are present in the cells in the same order of proportions as in my mixtures. I consider as untenable the comparison between the structures described by me and the manufactured nuclei and other artefacts known to "Every elementary student of physiology." The nucleus can be seen in the living cell; it appears whatever fixative be used; and though possibly distorted, it is demonstrable and recognisable whatever the treatment to which the material be subjected, short of practical disintegration.

Dr. Ludford gives "the reasons why most cytologists have come to regard the Golgi apparatus as a definite cytoplasmic structure." Many workers have done little else than describe 'Golgi bodies and apparatus'; these doubtless believe, and their faith is founded, on such reasons as those given by Dr. Ludford. But there are others who have claim to be classed as cytologists who do not, and never have, agreed with them.

I will deal with Dr. Ludford's reasons under the numbers which he attaches to them.

(1) The 'Golgi apparatus' seen in the living spermatocytes of Helix (Platner, Murray, no reference given), apart from almost certain *ante-mortem* changes taking place in the detached cells, may well be the archoplasmic vesicles which appear in the various stages of the meiotic phase, and are destined to form the cap of the sperm. They have been described as occurring in every animal specially investigated. Their destiny was known long before the invention of the 'Golgi apparatus' in anything but nerve cells, and they can be demonstrated with or without acetic acid in the fixative, presenting much the same appearance in both cases. It is claimed by the supporters of the 'Golgi apparatus' that it is present at any rate in all animal cells. These vesicles, so far as I know, have been described only in cells involved in the meiotic phase. I see no valid reason for connecting them with what Dr. Ludford and others understand by the term 'Golgi apparatus.'

(2) We are not dealing with mitochondria, and whether or not I agree with Dr. Ludford's statements regarding them, I am not attracted by this particular red herring. The rest of the paragraph is too indefinite to deal with categorically It is to be expected that some of the appearances claimed by Dr. Ludford and others as 'Golgi apparatus' may be structures that are really present in the cell (for example, the archoplasmic vesicles already referred to), and these would be demonstrable by both what he calls 'positive' and 'negative' methods. No doubt, also, anything that saturated the unsaturated fatty acid of the lipins would, under certain conditions, give a negative picture.

(3 and 4) These reasons were dealt with very fully in my paper (*loc. cit*, *supra*). Suffice it to say here that it has been shown that the lipin content varies enormously in the cells of different tissues, and to a less extent in the cells of the same or similar tissues, according to their physiological condition. In cells where the lipin content is large, so is the 'Golgi apparatus.' Not only does the amount of lipin vary, but the relative proportion of saturated to unsaturated lipins varies with the physiological condition of the cell, and with the tissue. In my mixtures the 'Golgi apparatus' varies according to the lipin content. In some it forms a "net-work," in others a "compact cluster round the sphere," besides assuming many other forms and positions described and figured by workers on 'Golgi bodies and apparatus.' By saturating the fatty acids one should be able to produce entirely 'negative' pictures. The 'positive' depend upon the degree of unsaturation of the lipins.

(5) I do not see why anyone should accept Dr. Ludford's statement that the "secretion granules of gland cells arise in relationship with the Golgi apparatus." Some quite competent cytologists believe, and a great number have believed during the past thirty years, that many of these granules are simply the result of the methods of fixation. Nor can I accept a statement as to the position of the 'Golgi apparatus' in relation to these granules as a valid argument in favour of its reality, when its very existence is the point in dispute.

If my interpretation of these various observations be correct, then the nature, function, and destiny of the Golgi bodies are less obscure, and we may be a little nearer to the solutions of the problems of fat transference and metabolism. Otherwise, excepting the archoplasmic vesicles of the meiotic cells, which can have, as I have tried to show, no relation to what 'most cytologists' regard as 'Golgi bodies,' there is no evidence, scarcely even a suggestion, as to the function, nature, or destiny of these structures, which are supposed to be present in all animal and many vegetable cells.

Liverpool, Feb. 7.

The Luminescence of the Dogfish *Spinax niger* Cloquet.

THE arrangement and the structure of the luminous organs of *Spinax niger* Cloquet have been thoroughly described by Johann.[1] Though these organs are present on the upper surface of the head and along the back (being distributed there mainly in association with the slime canals) they are enormously more abundant on the ventral surface of the body, and also on the flanks above the pelvic region, the black pigment, with which they are everywhere associated, forming a characteristic pattern on the skin of the fish.

I have very frequently handled Spinax at sea, and watched the luminescence of specimens taken from the trawl catch. When newly caught and vigorously alive, Spinax often shows no luminescence, nor are dead specimens luminescent. But while moribund, Spinax may show a greenish-blue light very distinctly visible to the dark-adapted eye.

Spots and streaks of light appear on the back of the fish, but their effect is very feeble compared with that of the belly, which appears as a steadily-glowing sheet of light, with brighter areas about the mouth, on the pectoral fin-bases, in the pelvic region, and on the tail fin. Th. Beer, who adds a note to Johann's paper, describing his observations on an injured specimen in the Naples Aquarium, says that the intensity of luminescence varied at short intervals, and was visible at a distance of 3-4 metres.

When a luminescent specimen is held so that one's line of vision is perpendicular to the ventral surface of the fish, the luminescence is plainly visible When the fish is then rotated slightly to left or right about its long axis, the light disappears. This observation seems to offer some explanation of the function of the luminescence of Spinax.

Johann's description and figures of the luminous organs show that each organ has a complex structure, complete with reflector, lenses, and iris-diaphragm of melanophores. Moreover, he shows that, while the organs in the middle line of the belly have their axes perpendicular to the surface of the skin, those situated on the flanks are also arranged with their axes parallel to the median vertical axis of the fish, and therefore make a considerable angle with the surface of the skin. This is carried to an extreme in the row of organs present on each side of the laterally compressed upturned tail. Here the organs lie with their axes almost parallel to the surface of the skin.

---

[1] L. Johann, "Über eigentumliche epitheliale Gebilde u.s.w. bei *Spinax niger*," *Zeitschrift f. wiss. Zool.*, 66, pp. 136-260, 1899.

The complex lantern-like structure of each individual organ seems designed to throw out a parallel beam of light, and to prevent scattering of the rays; the arrangement of the axes of all the organs parallel to the median vertical axis of the fish, seems to aim at precisely the effect described above, namely, that the luminescence will only shine upon objects immediately beneath the ventral surface.

The mouth of Spinax is situated remarkably far behind the tip of the snout, so that Spinax can obviously only seize objects immediately beneath (in the relative sense) its mouth. But it is only when an object is immediately below the ventral surface of the fish that the light from the luminous organs flashes fully upon it. One may therefore suggest that the sudden flash of light, at the moment of attack, may cause the prey of Spinax to hesitate for just that fraction of a second in which the mouth can make a successful snatch.

An Optical Paradox.

A paradox propounded at a meeting of the Physical Society may be of interest to a wider scientific circle.

Suppose that we have two lamp sockets, connected to perfectly steady electric supplies, clamped in fixed positions on an optical bench; exactly midway between these sockets is a photometer, also clamped. The photometer field, we will say, is divided by a fine vertical line into two parts, that on the left of the line receiving light only from a lamp placed in the socket on the left side of the observer, the part on the right of the dividing line receiving light only from a lamp placed in the socket on his right. Assume also that we have a series of lamps *A*, *B*, *C*, *D* . . . *Z* proceeding in finite steps from a lamp *A*, which emits at a definite rate light of a certain quality, to a lamp *Z*, which gives at some other rate light of some other quality.

We shall not be concerned with the ways in which the output of these lamps is to be measured quantitatively or qualitatively. Fechner's law applies to visual sensations, and we can therefore construct our finite sequence of lamps connecting any two given lamps *A* and *Z* in such a way that any two consecutive lamps of the series, if placed in the two sockets on our bench, will so illuminate their respective halves of the photometer field that the most critical observer can detect no difference between them. In other words, the visual sensations corresponding to the two halves of the field are identical. To say that the sensations differ by an amount so small that the observer is unconscious of the difference is to quibble.

Let us now suppose the lamps compared by an observer who is not subject to fatigue or other disturbing factor. We start with lamp *A* in the left socket and lamp *B* on the right. Each gives rise to the same sensation, which we will call *S*. Without in any way disturbing the system to the right of the photometer, we replace lamp *A* by lamp *C*. The sensations derived from the two lamps *B* and *C* are again identical, and since the system on the right is not in any way altered the new sensations are again exactly represented by *S*. We now leave the left-hand system alone and replace *B* by *D*; the previous argument applies without change, and the sensations are still *S*. The procedure indicated can evidently be carried as far as we like, and leads to the conclusion that any two lamps, *A* and *Z*, placed at the same distance from the photometer give rise to exactly the same sensation *S*. In other words, their candle power and their colour are the same, a conclusion which is absurd.

The significance of the paradox lies in the fact that the error in the argument arises from the neglect of a consideration widely ignored in scientific work. It should be observed that the experimental principles adopted, the use of a null indication and of simple substitution, are those most approved for precise measurements.

A Simple Form of Photo-electric Photometer.

Dr. N. R. Campbell (*Phil. Mag.*, **111**, pp. 945, 1041; 1927) has described a new method of using a gas-filled photo-electric cell by which small illuminations can be measured by the use of a telephone only. This method is, however, only applicable to gas-filled, and not to vacuum, cells; and for accurate measurements of strong illumination the latter are much more trustworthy. It is possible by using the well-known phenomenon of the intermittent discharge through a neon lamp to employ a somewhat similar method in the case of a vacuum cell. The circuit necessary is very simple. The photo-electric cell and the neon lamp are connected in series with a high tension battery of suitable voltage, and the neon lamp is shunted with a condenser. Under these conditions intermittent flashing will occur in the lamp when the photo-electric cell is illuminated, and the frequency of the flashes will increase with the illumination. It is accordingly only necessary to time this frequency to obtain a measure of the illumination. To do this it has been found more convenient to insert a telephone in series with the shunting condenser, and to count the clicks heard in it.

Some preliminary tests of the arrangement have been carried out, and they have shown that while the method is decidedly hopeful, it will need careful investigation before it can be considered reliable. The leakage current through the neon lamp before flashing occurs evidently limits the lowest illumination that can be detected. In the commercial Osglim lamp I have employed, this current appears to be unduly large, possibly due to insufficient insulation in the cap of the lamp. To obtain the best results it will probably be necessary to use special neon tubes. Leakage in the shunting condenser may also be troublesome. The sensitivity of the apparatus can easily be altered by using a variable condenser, and hence lights of very different intensities measured. It has been found, however, that the condenser should not be made too small, as then the flash discharge tends to become irregular.

If the method proves itself capable of yielding consistent and trustworthy results, it will undoubtedly be very useful for what we might call field measurements of daylight illumination with photo-electric cells. In these cases it is always inconvenient, and sometimes impossible, to use either a sensitive galvanometer or electrometer, and the only alternative is to employ some telephonic method such as has been developed by my brother, Dr. H. H. Poole (*Scientific Proc. Royal Dublin Society*, vol. 18, No. 9; 1925), in connexion with the measurements of submarine illumination. The new neon lamp method would be simpler, more portable, and much cheaper than this arrangement, and probably less liable to go out of order as it contains no moving parts. It remains to be seen, however, whether it can be made to give as good results.

The Excitation of Spectra by High Frequency Oscillations.

WITH reference to M. Ponte's letter in NATURE of Feb. 18, p. 243, may I say that my letter in the issue of Nov. 19, 1927, p. 727, did not pretend to be a full account of the development of the spectrum of mercury by the method of the electrodeless discharge, nor was it my intention to give the impression that I thought the phenomena observed were necessarily dependent on the short wave-length of the exciting oscillations. It was stated in that letter that the spectrum of mercury was examined as a preliminary to work on other substances; one of the advantages of this procedure was that mercury had already been studied by MM. E. and L. Bloch, using a similar method.

My results, however, differ from those obtained by these investigators in what I regard as an important particular. Apparently all the spectra which they photographed consisted of a large number of lines; the 'arc' lines appeared first, then the 'first spark' lines, and so on. On the other hand, I was able to develop the 'arc' spectrum in stages, first the triplet series, then the singlet series. This may have been due to the better control over the exciting conditions which is given by the valve method of generating the oscillations in the exciting coil. MM. Bloch themselves point out, in the paper to which M. Ponte (*J. de Physique*, **4**, 333; 1923) refers, that they could not keep the potential constant during an exposure. The method I used permits of this being done over a long period. This has the additional advantage that a steady temperature and pressure can be realised, with the coil activated, before an exposure is made.

The account which M. Balasse gives of his work with undamped oscillations is very brief; he says that he obtained the glow spectra of mercury, cæsium, and potassium, "which only showed arc lines." He does not mention any stages in the development of these arc spectra, and I look forward to a fuller account of this work.

M. Ponte attributes the absence of the *p* series "to the kind of discharge employed"; I suggested that it might be due to insufficiently high potentials applied to the exciting coil. Perhaps we may mean the same thing, for I observe that many of the lines recorded by MM. Bloch as 'spark lines' are members of this series. These spark lines were excited by increasing the length of the spark used in the production of the condensed discharge passed through the coil, and this lengthening of the spark involves a higher initial discharge voltage.

I would assure Prof. Bloch and his colleagues that I know and value their work. Nevertheless, the possibility of developing spectra series by series, not merely by stages of arc, spark, and so on, was new to me. It is the use of undamped oscillations at constant voltage which renders this possible because it facilitates control of the discharge, and it is this series by series development which I regard as full of promise.

The Exit of *Leishmania tropica* through the Proboscis of *Phlebotomus papatasii*.

IT has been shown (*Ann. Trop. Med. and Parasitol.*, vol. 19, No. 3, and vol. 20, No. 2) that human beings can be infected with *Leishmania tropica* by inoculation with Herpetomonas from naturally infected sandflies. It has also been shown that sandflies (*P. papatasii*) both wild and laboratory bred can be infected with *L. tropica* by feeding on oriental sores, and further, that after a certain period of development the artificially infected sandflies contain flagellates which on inoculation into man produce cutaneous leishmaniasis. The development of *L. tropica* in *P. papatasii* suggests very strongly that infection in Nature is through the bite of a sandfly, but actual experimental proof of the exit of the flagellates via the proboscis of sandflies has been hitherto lacking.

The following experiment proves beyond all shadow of doubt that *L. tropica* can be expelled from the sandfly via the proboscis.

19/1/28.—Seven specimens of *P. papatasii* ♀♀ (hatched in laboratory 17-19/1/28) fed through a membrane of rabbit skin on an emulsion of culture of *L. tropica* in inactivated rabbit blood (3000 per c.mm.).

23/1/28.—All the sandflies re-fed on a human being.

27/1/28.—One sandfly died, and on dissection was found to be heavily infected with *L. tropica*.

27/1/28.—Three sandflies re-fed through a membrane on inactivated rabbit blood. The experiment was performed at 37° C.

After the sandflies had fed, some of the inactivated rabbit blood was sown on a tube of Shortt's N.N.N. The remainder was examined microscopically. In nine coverslip preparations not a single flagellate was found.

2/2/28.—The inoculated tube was examined and found positive, that is, *L. tropica* had passed via the proboscis into the fluid above the membrane. The number of flagellates which had passed through must have been very small, because no flagellates were found in the coverslip preparations.

Further, under the conditions of the experiment, all possibility of fæcal contamination from the rectum of the sandflies was completely excluded.

The method of infecting sandflies by feeding through membranes has been described (*Ann. Trop. Med. and Parasitol.*, vol. 21, No. 2).

Further details will be given elsewhere.

Segmental Interchange and Crossing-over.

IN October last I published a working hypothesis for segmental interchange between homologous chromosomes (*Proc. Nat. Acad. of Sciences*, U.S.A., vol. 13, pp. 717, 718). Since that date, further work with liliaceous plants has led to an addition to this hypothesis.

It is presumed that the two strands of each homologue have breaks in the chain of genes at the leptotene stage (leptophase). These breaks are presumed to be at random in each of the two strands making up each homologue. The breaks are supposed to be only in the chain of genes, and not in the visible thread itself. They are to be regarded as places where the genes have separated far enough to be out of the sphere of mutual attraction.

In this case, if $1/x$ represents the probability of two breaks in any particular two of the four strands present at the zygotene stage (zygophase) coinciding, then the chance for such coincidence in any two of all four strands is $6/x$. One-third of these cases of coincidence will be between sister strands of the same chromosome. Hence the chance for coincidence between two breaks at a particular point in the twin halves of opposed homologous chromosomes is $4/x$. (The chance for coincidence between four such breaks, one in each of the four strands at pachyphase, is only $1/x^2$ at any particular point.)

In any coincidence of two breaks in strands of different homologues, for which the chance at any particular point is $4/x$, we may suppose that in half the cases the ends of the same threads are reunited, and in the other half of the cases ends of different threads unite, thus forming a chiasma. Hence the chance of a chiasma, or point of segmental interchange, between homologues at any one point in the bivalent is $2/x$. Since there is no chiasma between the other two strands, $1/x$ represents the chance of segmental interchange at any one point in the chromosomes resulting from the maturation division. (The occurrence of a second, or even a third, chiasma is to be allowed for.)

Hence $1/x = c/100$, where c is the observed percentage number of cross-overs between two adjacent genes.

Optically Excited Iodine Bands with Alternate Missing Lines.

WE have recently been studying, under improved conditions, the fluorescent bands which develop around the 'fundamental' doublets when iodine is excited, in the presence of helium, by the green mercury line. The use of a battery of four mercury arc lamps surrounding the iodine tube excites such a brilliant fluorescence that it is possible to photograph it in 24 hours in the second order of a 9-foot grating. On the plates so obtained it is apparent that only alternate lines of the corresponding absorption bands occur, namely, those for which m' is even. Now the fluorescent bands are known to be developed by collisions of the second kind between excited iodine molecules and helium atoms, wherein m' is changed from 34, the value originally excited, to various neighbouring values. The new data, then, show that the rotational quantum number of the excited iodine molecules can change only by even numbers during these collisions of the second kind.

This result, while incomprehensible on the classical Bohr-Lenz theory, is entirely in accord with the conclusions of the wave mechanics. According to the theory of Hund, successive rotational states of a symmetrical molecule, such as I_2, have, alternately, eigen-functions symmetric and antisymmetric in the two nuclei. Moreover, since the symmetric and antisymmetric eigen-functions correspond to different orientations of the spins of the two nuclei, and since these spins are presumably very loosely coupled, it is to be expected that transitions between symmetric and antisymmetric states will be very infrequent. In fact, Dennison has recently solved the long-outstanding problem of the specific heat of hydrogen by assuming that transitions between symmetric and antisymmetric states do not occur in appreciable numbers, even during the time it takes to make a measurement of specific heats.

The absence of the alternate lines in the optically excited iodine bands affords direct evidence in support of the theories of Hund and Dennison.

Absorption of X-Rays in Various Elements.

PROF. RICHTMYER, in a letter published in NATURE of Dec. 24, 1927, p. 915, states that he has formerly tried the formula

$$\delta_K = \frac{E_K}{E_{L_1}} \quad . \quad . \quad . \quad . \quad (1)$$

for the ratio δ_K of the absorption coefficients at the K-discontinuity. In the paper cited by Prof. Richtmyer (*Phys. Rev.*, 23, p. 292, Feb. 1924) he says: "This ratio is of the same order of magnitude as, but somewhat smaller than, the ratio of the energies required to remove a single K and a single L electron from an atom of the absorber." But the formula which contains the empirical facts, and given in my letter to NATURE of Nov. 12, 1927, p. 695, is not this one but

$$\delta_K = \frac{E_K}{E_{L_{\mathrm{I}}}} \quad . \quad . \quad . \quad . \quad (2)$$

Numerically, this formula (2) differs considerably from (1).

As the notations may easily cause confusion, I wish to point out the different meanings of the two equations.

There exists three energy-levels in the L-group which have been designed by L_1, L_2, and L_3, where L_1 is much more marked than the two others. In the system of notation introduced by Bohr these levels were designated by L_{III}, L_{II}, and L_{I} respectively; that is, L_1 corresponds to L_{III} and L_3 to L_{I}. The fact that L_1 (or L_{III}) is the most prominent level in the L-group might explain why the true formula (2) containing the less prominent level L_3 or L_{I} has up to this time escaped observation.

As will be seen from my doctorate dissertation, the experimental results found by Prof. Richtmyer also fit very well with the two laws described in my former letter.

Inflammable Gas from Plants.

IN Prof. Findlay's letter in NATURE of Jan. 14, he refers to Black's statement that "the *Dictamnus Fraxinella* emits" marsh gas "from its flowers," and asks for information on the topic.

Black undoubtedly alluded to *Dictamnus albus*, the fraxinella or dittany of southern Europe and central Asia, an old inhabitant of country gardens, which has showy, varicoloured, fragrant flowers. The plant is covered with glands that secrete a volatile oil, and in hot weather the air about the plant sometimes becomes inflammable therefrom.

According to Schimmel and Company (*Geschäftsber*, Oct. 1906) oil of white dittany contains 85 per cent. of pulegone, of which it smells strongly. Pulegone, or pulegenone, has been described by Semmler (*Ber.*, 35, 1022; 1902), and by Wallach (*Ann.*, 329, 125; 1903).

Engines.[1]

By Prof. E. N. da C. Andrade.

THERE is a certain appropriateness in 'Engines' as a subject for Christmas lectures at the Royal Institution. Most engines are machines for converting heat into work, and the first man to show experimentally the connexion between heat and work was Count Rumford, who founded the Institution in 1799. The original purpose of the Institution was "for diffusing the knowledge, and facilitating the general introduction of useful mechanical inventions and improvements; and for teaching by courses of philosophical lectures and experiments the applications of science to the common purposes of life." A course of lectures on engines certainly complies closely with this plan. While if it be urged that a physicist trained to occupy himself with vibrations and atoms should not meddle with things outside the usual scope of his studies, the physicist may, perhaps, without exposing himself to the absurd charge of arrogantly claiming kinship with so great a philosopher, point out that Thomas Young lectured at the Royal Institution on architecture and carpentry, on machinery, on hydraulics, and on what he called pneumatic machines, which included Newcomen's and Watt's engines, and the locomotive. In more recent times the present distinguished Fullerian professor of chemistry has lectured on trades. Precedent, then, is not lacking for the choice of so mechanic (using the word in the Shakespearian sense) a subject by a physicist.

Anything about engines has a claim on the attention of a juvenile auditory, but naturally with so vast a subject it is particularly necessary to have a very definite plan if the lectures are to be coherent. It was decided to make the course an illustrative commentary on the first two laws of thermodynamics, pointing out with a variety of examples how these laws operated, but carefully refraining from mentioning them by name, for fear of creating alarm and despondency in the juvenile ranks. The second law of thermodynamics may be held to be tough meat for the young, but it is perfectly easy to make boys and girls understand that you must have two different temperatures if heat is to be turned into work; to point out the two different temperatures in the case of each particular engine; and to show how there is always a striving on the part of the engineer to make the difference between these two temperatures as large as possible, because that enables us to turn the greatest fraction of our heat into work. The two laws were condensed in the phrases "Heat is work and work is heat" and "Lost temperature is lost opportunity," forms open, maybe, to criticism, but which proved convenient reminders of the substance of the rules. The last lecture was devoted to refrigerating engines, with the particular object of bringing home the essential character of the heat engine by showing what happens when it is driven backwards.

The chief difficulty in a course of Royal Institution lectures on engines is clearly the question of experiments and demonstrations. Some two hundred and fifty slides were prepared or borrowed, which helped to provide the necessary something-to-look-at. There is a certain number of simple experiments on mechanics and heat—on vapour pressure and steam, on explosions and on refrigeration—which can be conveniently shown to a large audience. Something more is needed, however, to give the lectures an engineering character, and that something was supplied by a large assortment of actual component parts of engines, and of models of engines and mechanisms, which the lecturer was fortunate enough to obtain on loan. Foremost among the lenders were the Science Museum, the director of which, Sir Henry Lyons, gave the most generous aid, and Mr. George Cussons, of Manchester, whose firm makes excellent working section models of all the chief types of engines and mechanisms, which proved admirably adapted for exhibition to a large audience. Loans from these sources were in evidence at nearly every lecture. Many other gentlemen[2] lent models of the products of their particular firms, models which proved a source of great interest.

In the first lecture, "The Rules which all Engines must obey," it was pointed out that, if there were no friction, the work done by any mechanism of pulleys, screws, or levers would be equal to the work done on the mechanism, but that, owing to friction, it was actually always less. A model hydraulic accumulator was used to emphasise the conservation of energy, and the meaning of power: a little pump slowly forced in the water which raised the accumulator piston, and then the energy so stored was quickly released to crush a cylinder of plasticine in a press. Talk of friction led to ball and roller bearing, and the Michell thrust block. A heavy wheel mounted on Skefko ball bearings (which, although it weighed some hundreds of pounds, turned to a silk handkerchief thrown on the spokes), and an air-lubricated model on the Michell principle provided practical illustrations. From the fact that diminished friction means diminished heat at bearings, passage was made to examples of great friction producing great heat, illustrated by the stock experiment of boiling ether in a rotating copper tube by friction against a wooden holder, the vapour blowing out a cork. Foucault's disc was used to show that, no matter how the resistance to motion arises, work done is turned into heat if no other effect is produced. Simple analogies of money changing were invoked to make clear the first law of thermodynamics. The fact that to convert heat into work special conditions are necessary was then simply discussed, and the second law presented from the point of view already mentioned.

---

[1] Summary of the one hundred and second course of Juvenile Christmas Lectures delivered at the Royal Institution on Dec. 29, 31, 1927, and Jan. 3, 5, 7, 10, 1928.

[2] Whose services will be acknowledged in the book which the writer is now preparing, to be published by Messrs. G. Bell and Sons.

In the second lecture, "Learning about Steam," the meaning of vapour pressure and the simple properties of steam—such as the variation of boiling point with pressure, and the difference between saturated and superheated steam—were explained. The experiments on this point included lighting a cigarette at a jet of superheated steam. It was pointed out that steam is only an intermediary in the conversion of heat into work, and has no magical virtues of its own, and, to emphasise this, model engines were made to work with alcohol vapour, hot air, and liquid air. The creation of a partial vacuum by condensation of steam was discussed, with special reference to condensers.

The elementary properties of steam having been exposed, it was possible to run rapidly through the early history of the steam engine. A model working on Savery's principle, and the Science Museum model of Newcomen's atmospheric engine, were shown. Attention was directed to the experiments and inventions of Watt, in particular the separate condenser, the closed-in cylinder, the double-acting engine and the governor. It was mentioned incidentally that Watt did not invent the steam engine. This has caused abundant comment, and has made it clear that the belief that Watt did invent the steam engine is much more widely spread than the lecturer supposed.

The third lecture dealt with the reciprocating engine. First of all, methods of changing reciprocating into rotary and rotary into reciprocating motion were discussed—crank, eccentric, cam, and swash-plate, or slant. This last, an invention of Watt's, is now applied in the so-called crankless engine. A few words were said on valves and valve gear, in connexion with which models built of Meccano strips were demonstrated. The consequences of the modern use of high-pressure steam, the main advance since Watt's time, were mentioned, and the meaning and advantages of compounding briefly explained. The marine reciprocating engine was illustrated by a very fine model lent by Mr. Scott, of Michell Bearings, Ltd., a model which roused enthusiasm and envy among the juveniles. The merits and demerits of the steam locomotive were then discussed, the flexibility on one hand, and the waste consequent on the lack of a condenser on the other hand, being among the points mentioned. The locomotives built for different purposes nowadays differ widely in design, a great contrast being, for example, provided by the enormous American articulated goods locomotives and the elegant high-speed 'crack' English passenger locomotives. The lecturer ventured to put in a word on the beauty of the modern locomotive, in which the English practical genius finds artistic expression, and encouraged boys to continue to admire such engines as the *King George V.*, the *Royal Scot*, and the *Lord Nelson*.

The fourth lecture dealt with turbines. The simplest principle of converting the energy of a moving fluid into energy of rotary motion was illustrated by the windmill, in connexion with which the question of best speed of running was raised. The de Laval turbine led from this to the principle of velocity compounding and pressure compounding. The difference between an impulse and a reaction turbine was illustrated by a model consisting of two bicycle wheels, to the rim of one of which small rockets could be fastened obliquely. When the rockets were lit, the wheel to which they were attached rotated rapidly by the reaction principle if it was free. If, however, this wheel was held, and the other wheel, provided with oblique cup-like projections, brought near to it, then the rockets blew the second wheel round by the impulse principle.

The services of Sir Charles Parsons, who was called the Watt of the turbine, were then outlined, and a large number of slides of different turbines and components were shown, in particular of the Chicago 50,000 kilowatt installation. The special problems of the marine turbine—reversing and gearing—were then indicated. Finally, the turbine locomotive was mentioned, with a special word on the condenser which is fundamental for such a machine.

The subject of the fifth lecture was the internal combustion engine, where the heat is generated in the cylinder itself. Some explosions of gaseous mixtures in long tubes served to illustrate certain fundamental points of the gaseous explosion, such as finite velocity of travel and the effect of confinement. The fundamental importance of the compression stroke was emphasised, and the question of 'knock' consequent upon excessive compression and of anti-knock substances briefly handled. After gas engine and petrol engine followed the Diesel engine, simple physical experiments being shown to demonstrate the heating of air by compression. Two beautiful working sectioned models, some seven feet high, lent by Messrs. Burmeister and Wain, helped to make the action of the Diesel clear. The lecture closed with a word about the Still engine and the new Kitson-Still locomotive.

In the last lecture the principles of refrigeration were discussed, both the absorption and the vapour-compression plan. Water was very rapidly frozen on the Carré principle, by the use of a modern fast-sucking pump. The important part played by mechanical refrigeration in modern life was stressed, examples ranging from mining to food preserving and from ice-making to oxygen-making being cited. After the principles of the vapour compression machine had been demonstrated, the two laws of thermodynamics were restated and now mentioned by name. A simple illustration was provided by the help of a step ladder and a pile of flat wooden blocks, painted 'heat' on one side and 'work' on the other. Starting with the pile at the top of the ladder, it was explained that one unit could be turned from heat to work for every step of temperature through which the pile descended, and the conversion was effected by lifting a block and turning it round. When the heat was at atmospheric level, refrigeration was produced, the heat being made to go up a step by turning a unit of work into heat, and adding it to the pile.

In conclusion, the lecturer put in a plea for the recognition of the importance of a sound foundation of physics for engineering students, and ventured to ask if, perhaps, a little too much stress was not sometimes laid on workshop experience and the 'start at the bottom and sweep up the shavings' precepts. He suggested that workshop experience could always be acquired, but that unless physics was learnt early in life, it was never learnt properly. He therefore told his young listeners that if they wanted to be engineers—good engineers—they must study the working of the few simple rules of mechanics and physics of the operation of which they had seen so many examples in the course of the lectures.

Voices Across the Sea.

A JOINT meeting of the Institute of Electrical Engineers in New York and the Institution of Electrical Engineers in London was held on Feb. 16, between 10.30 and 11 A.M. New York time, and 3.30 and 4 P.M. London time. The occasion was the discussion of a paper on trans-Atlantic telephony at New York. For this purpose the telephone system connecting Great Britain with the United States was employed. Loud speakers were used, so that everyone in the Council Room and Lecture Room of the London Institution heard with perfect distinctness everything that was said by the speakers Similarly, everyone in New York, at both the principal meeting and the overflow meeting, heard the speeches with perfect clearness, the disturbance from atmospherics being quite negligible.

Mr. Gherardi, the president of the American Institute, moved that Mr. Page, the president of the English Institution, take the chair at the joint meeting This was agreed to unanimously. Mr. Page then invited Mr. Gherardi to address the meeting. Mr. Gherardi said that in the auditorium from which he was speaking there were present about a thousand electrical engineers, who came from all parts of the New World. He said that, as the result of the accumulated work of the scientific worker, the inventor, and the electrical engineer, this joint meeting had been made possible. In particular he mentioned Faraday, Maxwell, and Kelvin as having laid the foundations on which their art was built. Starting in 1876 with instruments and lines which with difficulty permitted communication over a few miles, telephone conversation now spanned the Atlantic. It had added yet another tie to the many uniting the two electrical institutions.

Mr. Page in his reply said that he represented the thirteen thousand members of the English Institution. He spoke feelingly of the boon that Graham Bell gave to the world by the invention of the telephone. His memory, along with that of Franklin and Henry, will ever be cherished as benefactors of mankind. He paid tribute to the great American Institution which has contributed so largely to the progress of electrical science, and has proved over and over again that the benefits conferred by engineering are truly international.

Colonel Purves, the engineer-in-chief to the Post Office, said it was a privilege to participate in a pioneer demonstration of a wider use of telephony which would tend to bring nations into closer relationship. It was a great thing that two large assemblies, separated by a wide expanse of ocean, could join together in interchanging their thoughts and ideas by the simple and natural medium of direct speech. It will conduce to a better mutual understanding. As we sit and talk to each other our speech is launched into the air by the radio transmitting stations at Rugby and at Rocky Point with an electromagnetic wave energy of more than 80 horse-power. By various refinements and special devices the speech-carrying efficiency of each unit is many thousands of times greater than that of an equivalent amount of power radiated by an ordinary broadcasting station. General Carty, of the American Telephone and Telegraph Company, brought forward a motion to the joint meeting that it express feelings of deep satisfaction that recent advances in radio communication have made it possible to have international assemblies, which should prove to be powerful agencies in the increase of goodwill and understanding among the nations.

In seconding the motion, Sir Oliver Lodge pointed out the various causes that have contributed to the success of radio communication. In the first place, there was the invention of the telephone. Next, in order to transmit speech by ether waves it was necessary to harness electrons by a thermionic valve. That ether waves are constrained by the atmosphere to follow the curvature of the earth's surface is an unexpected bonus on the part of Providence, such as is sometimes vouchsafed on behalf of human effort. The actual achievement of to-day is due to the scientific and engineering skill of many workers, both those in the background and those whose names are familiar to the public. The motion was then put by the chairman and carried unanimously. The meeting was then adjourned, the chairman adding 'good-bye'

Before the joint meeting a film entitled 'Voices across the Sea' was shown, illustrating the processes that have to be gone through before a person in San Francisco can get into oral communication with a person in Plymouth. The path of the waves by the wires and over the ocean was indicated by luminous lines in motion. The delays at the various stations were also indicated, the whole operation before the lines were complete for speech taking only two or three minutes. From San Francisco to New York is by land line. The next link is to the transmitting station at Rocky Point, Long Island, then by radio to Cupar, and thence to Plymouth by land lines. The first link of the return journey is to Rugby, then by radio to Houlton, Maine, and so to San Francisco. The length of the radio link is about 3000 miles.

Obituary.

Prof. H. A. Lorentz, For. Mem. R.S.

Hendrik Antoon Lorentz, whose death on Feb. 4 has already been recorded in our columns, was the subject of an article by Sir Joseph Larmor in Nature of Jan. 6, 1923, when we had the privilege of reproducing his portrait in our Scientific Worthies series. Reference must be made to this article for a complete account of his scientific work and its significance in the progress of physics. It will suffice to state here that Lorentz was born at Arnheim, Holland, on July 18, 1853, and received his early training at the University of Leyden, where he became professor of theoretical physics in 1878. In 1902 he received the Nobel Prize for Physics; in 1905 he was elected a foreign member of the Royal Society; three years later he received its Rumford Medal, and in 1918 the Copley Medal. Such was his record; his personal qualities are described in the following brief messages with which we have been favoured.

Every student of the physical sciences knows the magnificent work of Lorentz: and his contributions have already been warmly and ably explained to the world. It may be justifiable to write a few words concerning the part that he played as a leader in international science, for that is less well known.

For many years Lorentz naturally and by general consent took the leading place in every European conference of physicists. He had won the affection and respect of men from all countries. He could use several languages fluently and accurately. He could grasp quickly the meaning of a speaker, and immediately on the termination of an address he could repeat its arguments and conclusions in such other languages as might be desirable, so that all present were kept in touch with one another. He never allowed a discussion to stray.

Nevertheless, even his great abilities and his sound judgment would not alone have made Lorentz the perfect president that he was. His success was due also to a wonderful and most attractive courtliness, to a humour that could express itself in not one language alone, and not least to the charm of a kindly and affectionate disposition. He was really beloved by all who sat under him. In his own field, and that no insignificant one, he was one of the forces that drew together men of different nations and brought them to a mutual understanding. W. H. Bragg.

In thinking of Prof. Lorentz one calls to mind, before all scientific achievements, his charming personality. A familiar figure at international and other conferences, speaking fluently several languages, he delighted everyone with his happy speeches and engaging simplicity of manner. There was no eccentricity of genius about him; he was just one of the simplest and most likeable of men. He must have wielded an immense influence, for he had come to occupy a unique place in the esteem of scientific men of all nations. Meeting him last autumn at the Conference at Como, I could see no sign of any failure of activity; and his mind was always young and able to enter with zest into the latest and most difficult advances of physics. In his long career he produced much work of the highest rank. The older work is now part of the commonplace matter of physics which we learn without thinking very much as to who originated it, and it is not easy to recollect at short notice the numerous developments that we owe to him. But his name recalls especially the Lorentz transformation, the culminating point of one phase of electrodynamic theory and the foundation stone of the next—relativity. I think it would be from about 1895 to 1902 that Lorentz and Larmor between them created a new chapter in electrodynamics. This development had two sides, one concerned with the effect of motion on all kinds of phenomena, and the other with the transition from Maxwell's continuous theory to the theory of electrons. I can well remember (as a student about 1905) how exciting was the escape from the old elastic solid ethers with their specific inductive capacities and other conventionalised conceptions to this new world of electrons. Lorentz's "Versuch einer Theorie" (the abbreviation is so familiar that one forgets there must have been some more of the title) alongside Larmor's "Æther and Matter" was the opening to the new physics; and what an opening it has proved! A. S. Eddington.

My own connexion with Lorentz, or rather with his works, goes back into a somewhat distant past. I took my degree at Cambridge in 1876, a few months after he had graduated at Leyden. A conversation with Stokes directed me to optics, Fresnel's wave surface, and the laws of double refraction as a first subject of investigation, and made me acquainted with Lorentz's dissertation on the reflection and refraction of light. From that time on I learnt to admire his work, and as the years passed on to recognise in him a master of physical science. Only some few weeks since I became possessed of the first volume of his lectures just published, and read again with increased feelings of regard and admiration some of that earlier work.

But to pass on. Lodge's paper on aberration problems aroused afresh the interest in the Michelson and Morley experiment of 1887; I think it was in June of 1893, when Fitzgerald was examining in the Natural Sciences Tripos along with J. J. Thomson, that he told us one evening in Thomson's rooms of his explanation of the difficulty—the brilliant baseless guess of an Irish genius we thought it at the time—he had given it in his lectures, he said, and then rather later we learnt of Lorentz's work and his paper in the *Transactions of the Amsterdam Academy of Sciences.* Little did we realise at that time all that was involved in the Lorentz transformation and his brilliant investigations into the laws of electromagnetism applied to moving média.

For me, however, much personal contact with Lorentz did not come until later; administrative work at the National Physical Laboratory severed in great measure my connexion with theoretical physics, but in 1922 I met him again at a meeting of the International Research Council at Brussels. The Council had been formed in 1919 to consist of allies and neutral nations replacing the former Association of Academies. Holland became a member at an early date, and Lorentz realised that, in many directions for the advancement of natural knowledge, the co-operation of the Central Powers was a matter of necessity. To this end he worked, feeling, as he wrote in 1925, that "the time had come to give as soon as possible to scientific effort that character of universality which, as a consequence of the nature of science, it ought to possess, believing that the action which he desired the Assembly to take would show a confidence in the future which could not fail to call forth a reciprocal feeling and assist in scattering the shadows darkening the life of nations."

Those of us who, in 1926, after the president, M. Emile Picard, had declared the proposal to invite Germany, Austria, Hungary, and Bulgaria to join the Council, to be carried by the unanimous votes of the 25 countries present, listened to his speech of thanks realised, if we had not known it before, that Lorentz was a great man, not only an eminent man of science, but also one who for his efforts in the cause of peace in science had fitly earned the gratitude of all who hold that on the growth of scientific knowledge depends the future welfare of mankind.

The International Research Council meets again in Brussels this summer. Is it a vain hope that at that meeting all nations may unite in doing honour to the memory of a man whose devotion to the cause of science has been so great, and whose work has proved a starting-point of one of the most marked advances of our time?

RICHARD GLAZEBROOK.

IN 1879, Maxwell was taken away in the prime of life, leaving behind him a mass of unfinished problems which seemed to call for the special genius of a Maxwell for their solution. It soon became clear that his mantle had fallen in a very special degree on the young Dutch mathematician who had just been appointed, at the early age of twenty-five, to the chair of theoretical physics at Leyden.

Lorentz took up in turn almost all the unfinished threads of Maxwell's work and carried them at least to the stage which Maxwell might have hoped to reach in a normal span of life, and often far beyond. He examined the effects of fine-grainedness of structure of media which Maxwell had treated as continuous; he took account of the mass of electrical charges which Maxwell had been content to neglect. These last investigations assumed great importance after the electron had been unearthed experimentally and established in its proper place in physics. Indeed, Lorentz's name is very specially associated with the mathematical theory of electrons, and his immediate explanation of the newly discovered Zeeman effect was one of his most sensational, although perhaps not one of his greatest, achievements. Whereas Maxwell had generally disregarded the effects of motion through the ether, Lorentz set to work to correlate the phenomena observable in systems at rest with those of systems in motion. He got so far as to show that the two sets of phenomena would be the same except for slight differences, imperceptible in practice, such as might be attributed to small (second-order) differences in clocks and measuring-rods. But this edifice needed for its consolidation a theory which ultimately came from other hands.

The aims of the two men were the same, but not their methods. Maxwell's science was an enchanted fairyland in which no one knew what magic would happen next. Lorentz's science was a workshop, in which tools of exquisite precision were fashioned with infinite care in view of all the world, and turned to their prearranged purposes; one almost seemed to see science growing according to plan.

Lorentz was beloved by all who had the honour of knowing him; the present writer can pay special tribute to his unfailing kindness and patience in discussing problems with men of a younger generation who had no conceivable claims on his time. Our admiration for his achievements is unbounded, but we will remember him mainly as our genial, kindly, and very human friend.

J. H. JEANS.

THERE is a remarkable unity, for the most part, in the work of Lorentz, converging as it does on the great purpose, to frame if possible a consistent theory of electricity and light and their mutual relations, and to clear up the obscurities inherent in these subjects, which are scarcely yet entirely dissipated. His studies on thermodynamics and radiation and gas theory may be recognised as all ancillary to the main purpose. To survey the titles alone of his published papers, in anything like a chronological sequence, is to recall the successive stages in a long endeavour which culminated in the theory of electrons and (in a restricted sense) of relativity. It is unfortunate from this point of view that the issue of his collected papers, begun in 1907, has not been continued. It was characteristic of the writer, though perhaps to be regretted on historical grounds, that he could not resist the very natural temptation, in a progressive subject, to revise and even to rewrite many of these by the light of further knowledge and reflection. It is to be hoped, in the interests of scientific history, that the publication will before long be continued and completed, as a fitting memorial of a great and effective genius.

The contents of the volume already published show that his interests were not wholly restricted to the speculations referred to, absorbing as these were. We find, for example, a paper on the turbulent flow of water in pipes. The theoretical work of Reynolds is here presented in a simplified form, and a novel attempt is made to find, on theoretical grounds, a limiting value of the 'critical velocity.' The paper was probably the first introduction of the matter to continental readers. We find, again, an elegant mathematical paper on viscous motion of fluids, in which a certain 'reciprocal theorem' is used to extend somewhat the range of soluble problems. There is also an interesting discussion of the Hertzian dynamics, which was attractive, no doubt, for the 'geodesic' principle on which it is based. Finally, we may mention an elegant article on the classification of crystal forms.

To British investigators, Lorentz was ever a most sympathetic figure. This was due partly to his mastery of our language, which made personal relations easy, partly to his keen admiration of the work of the great English leaders of his time (notably Maxwell), and above all to the transparent kindliness and charm of his character, with its strict integrity, and the engaging candour with which he always admitted and even emphasised such difficulties as he had not been able to surmount.

H. LAMB.

THE unexpected death of Prof. Lorentz, premature not in years but in intellect, removes from the world a gracious figure, that will stand in the range of succession of other past leaders—Volta, Davy, Ampère, Faraday, Hamilton, Stokes, Helmholtz, Kelvin, Kirchhoff, Maxwell, Rayleigh, Boltzmann, Willard Gibbs, Hertz, Poincaré—in the development of physical ideas, especially on the side of the consolidation of theory. The main characteristic which he exhibited, most prominently in recent years, has been great rapidity of assimilation, resulting in conciseness and clarity of exposition, over all the field of mathematical physics. This has always been a welcome feature to his colleagues in Great Britain, brought up, from the mode of their education, towards width of outlook. He was the ideal leader for an international congress, for he was the most learned and rapid of contemporary physicists. Of necessity, therefore, he took his knowledge from where he could most readily find it; and perhaps the work of the great originating minds of the British school was not so fully before him historically as it has been to their own countrymen—as indeed on occasion he has been the first to admit. When one considers his fifty years of scientific activity, absolutely in the front rank, the zest and power with which in recent years he has thrown himself into new phases of physical development, such as relativity and *quanta*, often problematical and perplexing to older modes of thought, have been most remarkable. He has been an outstanding ornament of the Dutch school, and of their historic university of Leyden: and when one looks around for his peers the name of Huygens is apt to rise to mind.

JOSEPH LARMOR.

THE concentrated power of the human mind is illustrated by the achievements of mathematical physicists more decisively than by any other pursuit The miracle does not lie in the working out of equations, but in the dissection and recognition of the essential operations of natural law with such completeness and clarity that the construction of equations to represent the intrinsic forces at work becomes possible. The deduction of consequences then naturally follows, or can be left to time.

In addition to analytical power, H. A. Lorentz had an exceptionally clear perception of the essentials of a physical process, and was able to state them with novel precision. He had thus the rare and enviable power of dealing with elementary and familiar facts in such a way as to interest advanced experts; for he could display unexpected connexions, and disentangle unforeseen contradictions, even in subjects which have long been taught superficially to first-year students. In this illuminating and clarifying power he has been likened to the late Lord Rayleigh, and the comparison is just. The difference was that Lorentz was a professor with worshipful students who took down and published some of his lectures, whereas Rayleigh had for the most part to range over the field of physical science by himself. Both clarified everything they touched. The way in which Lorentz's work dovetailed into, and often heralded, some of the modern developments—a search for invariants and the like,—his thorough grasp of the knowledge of his time, and his many steps over the border into new territory, have been dealt with in NATURE of Jan. 6, 1923, by a master mind: the only defect being that Larmor's own precursory or simultaneous contributions, which enabled him to appreciate so quickly the work of Lorentz, have been slurred over or ignored in that appreciative article.

In the past, too much of Lorentz's work has been partially buried in the *Archives Néerlandaises*, or has been made known only through lecture notes. A collection of his papers for English-speaking countries would be a great help; they might serve to recall attention to the physical bearing of some of the recondite speculations and revolutionary methods of treatment now in vogue, and help to re-establish connexion with much that has gone before.

Where so much has been done, it may seem trivial to pick out a single instance of Lorentz's scientific insight, but I was personally concerned in verifying the Zeeman dissection of spectrum lines by a magnetic field, at an early stage ("Yearbook of the Royal Society for 1897," 98, p. 119), and could appreciate the almost contemporaneous electron-orbit precessional theory of Lorentz. It is well known that he anticipated or predicted a number of subsidiary details, about polarisation and the like, which were forthwith abundantly verified by observation.

I had the pleasure of entertaining Prof. and Mme. Lorentz at Edgbaston on the occasion of the conferment of an honorary degree, and they became our valued friends. With his scientific or philosophic outlook I found myself in close sympathy.

OLIVER LODGE.

I CANNOT pretend to write any appreciation of Lorentz's scientific work. I have only known him as chairman of a small international body of which I am a member, the committee set up by the League of Nations to provide the machinery of international co-operation, when required, in questions of science, arts, and letters. It is generally known as the C.I.C. or Committee of Intellectual Co-operation.

The first chairman was the philosopher Bergson, a swift and subtle thinker, a man of infinite accomplishments, accustomed to the great world, and a speaker of distinguished eloquence, equally at home in French and English. When Bergson retired, it seemed almost impossible to fill his place, until someone—I have been told it was his pupil Einstein—suggested the name of Lorentz. He was not at the time a member of the committee, but as soon as he came among us he impressed all his colleagues as the right man. He had not the brilliance or the diplomatic power of Bergson; but his patience and courtesy, his imperturbable fair-mindedness, his transparent simplicity and goodwill, together with his great scientific eminence and his easy command of English, French, and German, gave him at once the entire confidence and affection of the committee. He had the advantage, of course, of coming from a neutral country; he had no old enmities to forget, and his own devotion to the cause of international appeasement and common sense was so obvious that one never spoke of it. It could be taken for granted.

All the multifarious undertakings of the committee come before the chairman, and Lorentz had to arrange for the consideration of problems of bibliography, of art, and even of law, as well as of science proper. He never failed in lucidity and never lost patience. But above all he enabled his literary colleagues to understand and appreciate the noble simplicity of a great mind genuinely devoted to science. Gilbert Murray.

All physicists, young and old, realise and appreciate the importance of Lorentz's work. Those who are old enough to be his contemporaries, who read his papers as they appeared, or rather as they were translated, who know the views prevalent before they came out and the changes they produced, can perhaps realise more easily than the younger men the effect of his work and the magnitude of the influence it has had on the progress of science. This feeling will be especially acute in those who more than fifty years ago were convinced of the truth of Maxwell's theory of light and interested in its development, for Lorentz was the first pioneer of Maxwell's theory.

Lorentz's first work, a dissertation for the doctor's degree in 1875, was an application of Maxwell's theory to the problem of the reflection and refraction of light by dielectrics and also by metals. This, so far as my knowledge goes, was the first application of Maxwell's theory other than those made by Maxwell himself. This was followed by a still more important paper on the relation between the refractive index and the density of bodies; this was the first application of Maxwell's theory to a medium consisting of discrete molecules which could be polarised by electric forces. We have in the same connexion his great memoirs, "La Théorie électromagnétique de Maxwell et son application aux corps mouvants" (1892) and "Versuch einer Theorie der elektrischen und optischen Erscheinungen in bewegten Körpern" (1895), the second of these being the beginning of the great subject of relativity.

There is no space here to discuss Lorentz's work in any detail; it covered so much ground and his papers throw so much light on the state of scientific opinion when they were written that an edition of collected papers, which it is to be hoped will be one of the ways in which his memory will be commemorated, would supply invaluable material for the history of physics during the past half-century.

Lorentz's services to science were not confined to his own researches; he was an admirable expositor in many languages. Those who heard him give in 1923 the Rede Lecture in Cambridge on Maxwell's electromagnetic theory will remember that without any notes he spoke for an hour in perfect English, never hesitating for a word. In addition to expressing his own ideas clearly, he was remarkably quick at understanding the ideas of other people, and often, though he might not agree with them, put them more clearly than their author. These qualities, combined with unfailing courtesy and kindliness, made him unrivalled as the chairman at a scientific conference. He was, I should think, the most cosmopolitan man of science that ever lived. He travelled widely in many countries, and there can be but few universities either in the Old World or the New in which he had not lectured and inspired and encouraged both teachers and students, and stimulated them to undertake further investigations. Besides his own researches, great as these are, science owes to him many others of which he was directly or indirectly the begetter. J. J. Thomson.

The news of Prof. Lorentz's death will be heard with deep regret by many friends in England and Scotland who had come under the influence of his remarkable personal charm, and admired him for his grace, sincerity, and kindliness, no less than for his great scientific achievements.

Lorentz's fame will, I think, ultimately rest chiefly on his electron-theory and all that followed from it. The essential characteristics of this theory were that all electric, magnetic, and optical phenomena were supposed to be due to the presence or motion of individual electric charges, constituting the link between ponderable matter on one hand, and the ether on the other. Matter and ether were supposed not to interact directly, and to be capable of influencing each other only through the mediation of electrons: moreover, the electrons were assumed not to interact directly (as they had been supposed to do in the older electron-theories), and to be capable of influencing each other only through the mediation of the ether. The ether itself was conceived to be at rest everywhere and at all times, whereas in the earlier theories it had been regarded as entangled with the particles of bodies, and carried along with these when they move: Lorentz's ether was, in fact, merely space endowed with certain properties. The general plan of the investigation was to reduce all the complicated cases of electric and magnetic action, *e.g.* the properties of dielectrics, metallic conduction, metallic reflection, the Hall effect, etc., to one simple and fundamental case, in which the field contained only free ether with electrons at rest or moving in it.

The theory was remarkably successful, unifying and simplifying everything, and, in particular, reconciling the electromagnetic equations with Fresnel's law of the propagation of light in moving bodies. But it was, in its original form, incompetent to explain the negative result of the Michelson-Morley experiment: to meet this difficulty, the additional hypothesis of the Fitzgerald contraction was adopted in 1892: and in 1895 Lorentz made another advance on the road to relativity by introducing the idea of 'local time.' Larmor in 1900 extended the analysis so as to include small quantities of the second order, and thereby discovered the connexion of Lorentz's theory of local time with FitzGerald's contraction: and in 1903 Lorentz went further still and obtained the exact transformation which is known by his name and is the basis of the theory of special relativity. The principle of relativity itself was first clearly enunciated in the following year by Lorentz and Poincaré, especially in the latter's address delivered in September 1904 before the International Congress of Arts and Science at St. Louis. To the subsequent development of the subject Lorentz made important contributions, though perhaps none so epoch-making as his great discoveries of the period 1892–1904.

E. T. Whittaker.

News and Views.

The Bill for the Stabilisation of Easter was advanced a stage in the House of Commons on Feb. 17, when, on the motion of Captain Bourne, seconded by Mr. Withers, it was read a second time. Following the suggestion of the League of Nations special committee of inquiry, the proposed date for Easter is the Sunday after the second Saturday in April, the purpose of this provision being (1) to make the festival coincide as nearly as possible with what appears to be the actual date of the event commemorated, and (2) to avoid the clashing of Passion Sunday with the Feast of the Annunciation (as actually happens this year when Easter falls on the second Sunday). Some of the speakers opposing the Bill urged that meteorological conditions are apt to be unfavourable at the period named, but such objections must be completely outweighed by a consideration of the historical grounds on which the proposed date has been chosen and the fact that Easter is a festival for all countries. A point which emerged clearly in the course of the debate is that the promoters of the Bill have no desire to override the ecclesiastical authorities. The Bill itself provides that it shall not come into operation without an order in Council, so as to give an opportunity for arrangement with the Churches, and the Home Secretary, in supporting the Bill, remarked that its promoters were willing to strengthen this safeguard by inserting a further clause under which such an order shall not be made without a resolution by Parliament in its favour. The Bill was actually a response to the desire of the ecclesiastical authorities for assurance that the stabilisation of the festival is demanded, and the Home Secretary said that its acceptance would be regarded as an instruction to set to work on the requisite negotiations. Sir H. Slesser, who had moved the rejection of the Bill, then withdrew his motion.

As regards the meteorological side to the problem of choosing the best period for a fixed Easter in April, statistics show that there is a slight general tendency over Great Britain as a whole for more rain to fall as the month grows older. This is due, no doubt, to the fact that the heating effect of the sun, and consequently the average temperature of the lower layers of the atmosphere during the middle of the day, is increasing rather rapidly, in consequence of which convectional rain of the type of the thunder shower becomes more common. This tendency is, however, too small to be of much practical importance. Some meteorologists believe that a sudden set-back of temperature is particularly liable to take place at certain fixed times in the spring and early summer, but even if this belief can be justified statistically—a matter of some doubt—the regularity of recurrence of these set-backs is not sufficient for the effect to be worth taking into account. That abrupt changes from summer warmth to winter cold do take place in most years at least once between the beginning of April and the end of May, is a matter of common knowledge, but it seems probable that this effect is associated with a marked annual variation in the frequency of occurrence of anticyclones over Greenland. The northerly or north-easterly winds that bring the cold weather normally descend to temperate latitudes along the eastern margins of such anticyclones; the maximum frequency is reached in May, and although a gradual increase takes place in the course of April, which gives the early part of the month some slight advantage, this is more than outweighed later by the greatly increased length of the day, and by the fact that not only does the earth then receive more heat and light from the sun, but also a higher proportion of the ultra-violet radiation, without which no holiday can be regarded as ideal from the point of view of health.

The Galton Lecture delivered on the anniversary of Sir Francis Galton's birthday is an annual feature of the Eugenics Society. The lecturer this year was Dr. C. J. Bond, of Leicester, who chose as his subject "The Distribution of Natural Capacity in the Population and the Need for a National Stocktaking." Though it cannot be said that Dr. Bond introduced his audience to any new ideas, yet he gave forceful expression to several well-established ones at present too much neglected. He pointed out that in all societies aristocracies tend to die out, and that the great reservoir of vigour from which the life of the nation is recruited is to be found in the middle class. Since this class consists of those who by their energy and perseverance have raised themselves to a position of financial independence, and since in the last resort the life of the nation rests on the daring and enterprise of its citizens, this is what might be deduced from *a priori* consideration. The younger sons of middle-class families who go abroad on errands of commercial enterprise or colonial government are the legitimate successors of the merchant adventurers of Queen Elizabeth's time, who, although they used more questionable methods for the promotion of British trade, were the real founders of the British Empire. Dr. Bond pointed out, however, that the middle class is losing its reproductive capacity, and he attributed this chiefly to the practice of voluntary birth-control. The motive inducing this practice is largely the desire to avoid being crushed by the taxation levied on them to supply the needs of what Dr. Bond called the degenerate class—the cancer-cells of the social organism who reproduce recklessly without any thought of the morrow, and propagate stupidity and laziness from generation to generation. Dr. Bond's remedy is to give free knowledge of the means of birth-control to all who desire it, and if this is ineffective he boldly advocates the ultimate sterilisation of the thriftless. Though Dr. Bond's views may be unpopular in a sentimental age, the nation which neglects them is doomed to decline and degeneracy.

DR. BOND's plea for a 'stock-taking' or mental and physical measurement of the population, introduced more questionable considerations. The ultimate test of the fitness to survive which Nature applies to the citizen is his ability to maintain himself under existing conditions—in ultimate analysis, fitness is economic fitness. Leaving aside the pathological cases of the victims of hereditary disease or mental weakness, who only constitute at the worst a small percentage of the community, it seems to us impossible to devise an arbitrary test which shall separate the fit from the unfit. The Simon and Binet mental tests have proved disappointing in practice: often those whose response to these tests indicates a low mental age, prove better able to maintain themselves in the struggle for life than their supposedly better intellectually equipped brethren. Differences of physical development may be partly due to 'inborn characters,' but we are constantly receiving shocks in discovering that what were considered to be hereditary defects are really due to the handing on from generation to generation of bad diet and bad air. Dr. Bond rightly compared the aberrancies of human population to the 'sports' in domestic animals. He did not reflect, however, that 'sports,' although hereditary, must owe their origin to definite causes, and that the evidence before us justifies the belief that when these causes cease to operate the 'sport' ultimately reverts to the wild type. The ultimate cause of many of the physical defects in the population of England is overcrowding, due to over-population. When this is remedied such defects will disappear, if not entirely in one generation, at any rate in two or three.

PROF. HUGH S. TAYLOR, of Princeton University, has been awarded the Nichols medal for 1928 by the New York Section of the American Chemical Society. The medal, awarded for "the research published during the current year which in the opinion of the jury is most original and stimulative to further research," will be made to Prof. Taylor at a gathering of American chemists in Rumford Hall, 50 East 41st Street, on Mar. 9, when he will deliver an address on "Catalysis as an Inspiration of Fundamental Research." Prof. Taylor, who is widely known for his studies in catalysis, holds the David B. Jones research professorship of chemistry in Princeton, a chair founded last year by Miss Gwenathlyn Jones, of Chicago, in memory of her father, David B. Jones, and as part of the newly organised endowment for scientific research in Princeton. Prof. Taylor is English by birth and was educated at the University of Liverpool, and at the Nobel Institute, Stockholm, under Arrhenius, where he made his first investigations on catalysis, and at the Technische Hochschule at Hanover, where he carried out investigations with Prof. Max Bodenstein on photo-chemistry and reactions produced by the α-particles from radium. Prof. Taylor went to Princeton early in 1914 as instructor in physical chemistry and was made assistant professor in 1915. During the War he was employed on munition work by the Government of Great Britain on problems relating to the fixation of atmospheric nitrogen for use in explosives.

ON his return to Princeton in 1919, Prof. Taylor initiated a wide programme of research on the physical and chemical properties of the catalytic materials used in such important catalytic industries as ammonia synthesis, the hardening of oils to produce edible fats, and the more recent industrial synthesis of wood alcohol or methanol. This work led to the formulation, in the *Journal of Physical Chemistry*, in 1925, of a theory of the catalytic surface which is now accepted generally by students of catalysis. In attempting to explain the acceleration of chemical processes occurring at such surfaces, it was postulated that the reacting elements might exist on the surface of catalysts in the atomic condition. This was demonstrated experimentally and led to a study of the properties of free atomic hydrogen. In this work new methods of producing hydrogen peroxide and formaldehyde were worked out, the industrial applications of which are being studied in the United States and in Germany. During the last two years Prof. Taylor has been chairman of the Central Petroleum Committee of the U.S. National Research Council, in which capacity he has charge of the allocation of grants from the 500,000 dollar fund created by gifts from John D. Rockefeller, sen., and the Universal Oil Products Company for the promotion of fundamental research in the physics, chemistry, and geology of petroleum. In this connexion he has recently devoted considerable attention to the scientific problems involved in the conservation of gas and oil in the recovery of oil.

Prof. Taylor is the author, with Dr. E. K. Rideal, of "Catalysis in Theory and Practice," the editor and part author of a "Treatise on Physical Chemistry," and has written monographs on "Industrial Hydrogen" and on "Fuel Production and Utilisation."

WICKEN FEN, half-way between Ely and Newmarket, promises to become one of the most interesting of the reserves held under the National Trust for Places of Historic Interest or Natural Beauty. The history of old England lies in its sedge beds and is embedded in its peat, and the old story since the days when the walrus sported in the sea which covered the Fen area, lies, complete and untampered with by the hand of man, awaiting the unfolding of the naturalist. In a pamphlet which accompanies a new part of the "Natural History of Wicken Fen," Prof. Stanley Gardiner shows how circumstances have conspired to retain this aboriginal inlier in the midst of an area which man has interfered with, at latest since the Romans began to drain the marsh. A very large area of the marsh has been recovered, but, because of its position as an area for drainage concentration, Wicken Fen has not only never been cultivated, but also has never been deliberately drained. So that, if its peat layers retain the relics of successive faunas of prehistoric times, the Fen itself retains, so far as may be, the original fen fauna of earliest historic England. It may be said that similar native areas are to be found in the wilds of the Scottish Highlands. But there is a vital difference: Scottish and other moorland marshes are saturated with acid waters which breed their own special flora and fauna; Wicken, peculiar in possessing alkaline water, stands at the opposite pole as regards the composition of its plant and animal life. For this reason alone, it is worthy of preservation and investigation; but when it is added that it contains the relics of an old flora and fauna now rapidly disappearing, and that it offers almost the only opportunity of interpreting the changes which the centuries have wrought in the fen assemblages which predominated over a large part of ancient England, the need for preserving it intact for present and future generations becomes insistent.

UNFORTUNATELY, this keeping intact is not so easy of accomplishment at Wicken as in many another reserve. The sedge, under the deliberate cropping of centuries for the thatch of houses, grows so strongly that if left uncut it forms a tangle impenetrable to the delicate bills of wading birds, which nest in summer and resort in multitudes to the marsh in winter. Brushwood, which has conquered much of the surrounding land and has there reduced the fauna from about 6000 to less than 2000 species, gradually intrudes and has to be uprooted. Gunmen hire adjoining areas, and, like the professional collectors of rare insects and rare birds and their eggs, regard the abundance of preserved creatures as a godsend, and make the most of opportunities they have done nothing to create. Watchers must be hired to keep them at bay, an expensive item, which would be reduced if the outlying areas abutting on or penetrating into the reserve—and some are already derelict—could be purchased as they come into the market. The recurring annual upkeep and the need for non-recurring expenditure in purchasing such desirable extensions, cannot be met by the funds at the disposal of the local committee. We understand that the National Trust is at the present moment issuing an appeal for such sums as would make Wicken Fen a permanent and worthy acquisition for the nation and an inestimable boon to the naturalist and the scientific student of ecology and of the history of England's fauna and flora. Most heartily we commend to the attention and generosity of our readers this appeal, copies of which may be obtained from the secretary of the Trust, 7 Buckingham Palace Gardens, London, S.W.1.

A SECOND annual report upon "Bird Sanctuaries in Royal Parks in Scotland," by the Committee appointed by Viscount Peel, has just been issued by H.M. Stationery Office (Price 6*d*. net). It shows how effective, even in the course of a couple of years, may be the planting of suitable cover and food plants and the protection of an area in inducing the presence of additional species of birds. At Duddingston Loch, within the precincts of Edinburgh, twelve additional species nested during the summer of 1927, and five birds, not before recorded, visited the sanctuary, including a goldfinch, attracted by teazle which had been planted during the spring. It is now considered that sufficient additional cover has been provided. The population of this interesting area, which is particularly favoured by hosts of immigrant ducks during the autumn and winter, now numbers 39 nesting species, 33 regular visitors, and 23 casual visitors. The Committee has wisely enlisted the co-operation of local naturalists by appointing several recognised ornithologists as official observers. Further, in order that a scientific study of the inter-relationships of plant and animal life, and of the changes in fauna and flora brought about through the reversion of the sanctuary to a state of Nature, may be made, the Committee has in addition instituted a botanical and entomological survey of the area. In this it is fortunate to have enlisted the help of the officers of the Royal Botanic Garden, Edinburgh, and a summary of a detailed report on "The Plant Life of Duddingston Loch," by Mr. J. R. Matthews and Mr. G. Taylor, is appended to the Report.

IN a further lecture "From Faraday's Note Books" at the Royal Institution on Feb. 16, Sir William Bragg stated that Faraday's work on gold films and gold suspensions is one of the fundamental researches of the subject. He chose the subject for his Bakerian Lecture before the Royal Society in 1857; and few Royal Society papers have been more widely read and quoted. Curiously enough, his first inquiries were made without any consideration of the rich system of gold colours; and of course with no idea of the ultimate importance of his work to colloid chemistry. He wished to enter the field of research opened up by the then recent discoveries belonging to the undulatory theory of light. He thought that if he could investigate the action upon light of particles or films which were so small or so thin that several of them could be contained in the length of a wave of light, then some special phenomenon might be found which would help him to extend the new theory. His thoughts turned towards the use of gold leaf; and he arranged for a visit to his friend Mr. Warren de la Rue, the well-known printer, who was the fortunate possessor of a fine microscope; and on Jan. 27, 1856, they "had a good evening together." This was the beginning of several months of hard work. His laboratory notes fill hundreds of pages; and hundreds of the specimens which he made still remain at the Royal Institution, carefully arranged and indexed. The problem opened out in unexpected directions. He was never able to co-ordinate completely all the extraordinary observations which he made; nor indeed has modern theory been able to complete the task with all satisfaction. It did not throw much light on the undulatory theory, but it has been invaluable to the colloid chemist engaged in an attempt to unravel the mysteries of one of the most complex, fascinating, and important of all the sciences.

The publication of the first number of *Africa*, the journal of the International Institute of African Languages and Cultures, will afford a wider public an opportunity of appreciating the importance of this movement for placing African studies on a broader basis. In present conditions, political and other, international co-operation and co-ordination are essential in the solution of the many-sided problems presented by Africa. This is as true in the field of purely scientific research as it is in the domain of the practical problem of administration. Mr. Driberg, for example, in this number, in discussing primitive law in eastern Africa, emphasises the danger of generalisation from data which extended observation may show to be sporadic only, and perhaps even restricted to a certain area. The success of the Institute and the measure of support it may expect will depend upon the extent to which it is able to promote investigation on these lines, otherwise it merely enters into competition with existing organisations which deal with African studies. Its aims, as formulated here by Sir Frederick (now Lord) Lugard, are admirable, especially in so far as attention is to be given to the practical bearing of research on economic and administrative questions. Excellent as is the first number of *Africa*, however, it cannot be said that all the papers are of the type which might most usefully be published by the Institute; but Mr. Driberg's paper already mentioned, and Capt. Rattray's article on "Anthropology and Christian Missions," are very much to the point.

Invitations are to be sent out shortly for the next meeting of the International Astronomical Union, to be held at Leyden on July 5-13 of this year, together with the provisional programme of the meeting. The president of the Union is making use of his statutory prerogative to invite persons belonging to nations that have not yet joined the Union, and it is expected with certainty that many of these will accept the invitation. The Leyden meeting of the Union will thus be the first of the congresses of the unions founded under the auspices of the International Research Council, that will be completely international in character and in which representatives of science belonging to countries that stood on opposite sides during the War will meet in a spirit of international brotherhood.

In all fields of biology the importance of accurate measurements and quantitative data is being increasingly realised. Much work is not infrequently rendered useless, or at least much less useful than it might be, through neglect of simple precautions in the making, recording, analysis or presentation of such data. A committee of Section D (Zoology) of the British Association has concerned itself with these matters, and has issued a valuable report in which important recommendations are made. The committee found that the satisfactory presentation of statistical data is often impaired by the reluctance of editors to print extensive numerical data in full, and negotiated for the establishment of centrally placed archives for the reception of original data too extensive for complete publication. The Natural History Museum at South Kensington and the Royal Society of Edinburgh have both agreed to undertake this function. The data thus deposited in these archives will be available to students, and in this sense will have secured effective publication.

The leaflet which has been issued by this Committee consists of a foreword illustrating the needs of biological work, followed by sections on (*a*) the planning and execution of research by metrical methods, (*b*) the methods of compact presentation of data and the recognised methods by which it can be adequately summarised, (*c*) the interpretation of statistical results and tests of significance, and (*d*) detailed references to text-books on the several types of tests generally required. The leaflet will be of the greatest possible service to biological workers, and should go far towards securing uniformity in the compilation and presentation of statistical data. It deserves to be widely known among workers in this field of biology.

Some new picture postcards have been placed on sale at the Royal Botanic Gardens, Kew. The most interesting is probably a view of the Iris Garden, in natural colours, showing the beds of Iris in full bloom. Other pictures include *Angræcum sesquipedale*, an orchid which has a nectary up to 1¼ feet in length: *Dendrobium thyrsiflorum*: *Prunus Lannesiana*. There is a set of six pictures in colour, representing several kinds of brilliantly coloured water-fowl which inhabit the neighbourhood of the pond; also a set of seven black-and-white cards showing some of the ornamental geese which are to be found near the lake. This set includes a picture of "Joey," the handsome Stanley crane which must be familiar to most visitors during the summer months. The prices are 6*d*. for a set of seven black-and-white cards, and 1*s*. for a set of six coloured cards with descriptive leaflet.

A very interesting feature of Section K at the Leeds meeting of the British Association in September last was Dr. Lotsy's demonstration of wild hybrids from various parts of the world, which attracted so much attention that it had to be twice repeated. The importance of such investigations, especially in relation to Dr. Lotsy's well-known views on the rôle of hybridisation in evolution, is so obvious as to require no special emphasis, and Dr. Lotsy is to be congratulated on the accumulation of a wealth of highly interesting material. Starting with coloured drawings illustrating the wide diversity in the second generation of crosses made in his own experimental garden between two varieties of pumpkins and between *Tragopogon pratensis* and *T. porrifolius* respectively, Dr. Lotsy proceeded to demonstrate the occurrence of similar hybrid swarms in Nature. In the first place, he showed a series of coloured drawings of segregates from the spontaneous cross *Primula auricula* × *P. viscosa*, found on the Weisshorn near Arosa, and prepared by their discoverer, Dr. Knoll. As an American example he demonstrated the wide range within certain species of Opuntia observed by him around Tucson in Arizona in connexion with Dr. MacDougal's investigations on artificial Opuntia-hybrids.

Many of the examples used in Dr. Lotsy's demonstration were obtained in New Zealand, partly by Dr. Lotsy himself during three months' exploration of both islands under the invaluable guidance of Dr. L. Cockayne, the pioneer in this field in New Zealand, and partly by Dr. H. H. Allan, of Fielding, and Messrs. A. W. Thomson, J. Scott Thomson, and G. Simpson, of Dunedin. Even a three weeks' stay in Australia afforded some interesting cases, thanks to the help of Profs. Lawson and Osborn, as well as of Messrs. S. L. Kessel and C. A. Gardner, of the Forestry Department, and of Mr. W. H. Carne, of the Department of Agriculture, Perth. Finally, Dr. Lotsy showed a fine collection of coloured drawings by Dr. Goddyn, both of plant hybrids and of hybrids between different human races, from South Africa. In obtaining these he was materially assisted by Prof. Schönland, Dr. Marloth, and Mr. Dyer, of the Botanical Survey. In concluding, Dr. Lotsy expressed his great indebtedness to the many who assisted him in the search for wild hybrids, either directly or by extending hospitality to himself and his party, and also to the governments of the three Dominions who materially aided his investigations by providing free railway passes and other facilities.

Many of us who scan the posters of the Empire Marketing Board may be inclined to ask whether, and to what extent, the Board is assisting the British agriculturist to extend his markets. These and other questions are answered in a pamphlet, "The Empire Marketing Board and the Home Producer," which will be sent free to any inquirer by the Board on application to its offices, 2 Queen Anne's Gate Buildings, Dartmouth Street, London, S.W.1. In this pamphlet the Board outlines briefly the methods by which, directly or indirectly, it has given real help to the British farmer, as distinct from the Colonial agriculturist. Its posters have advocated "home buying first"; grants have been made to the Ministry of Agriculture to enable the Ministry to conduct investigations into improved methods of packing, grading, and marketing produce (some of these, no doubt, based on the best experience of the Colonial producer); while the Ministry of Agriculture has, in turn, made substantial grants to various fruit growers' associations and agricultural research departments. Grants have also been made direct by the Empire Marketing Board to the Scottish National Milk and Health Association to enable the latter to carry out large-scale experiments on the feeding of school children in various Scottish centres upon milk, and to increase the consumption of milk in Scotland, while in Northern Ireland it is co-operating in investigations into the marketing of Northern Ireland butter and eggs. The Board is also now issuing a series of *Weekly Fruit Intelligence News*, to keep the British consumer up-to-date in the matter of supplies from the Colonies. Any one further interested in the work of the Board is recommended to obtain a free copy of the first report, "A Year's Progress," which gives fuller details of grants made and the research and other work to be covered by such grants.

The annual Congress of The South-Eastern Union of Scientific Societies will be held at Rochester on June 6-9 inclusive, under the presidency of Sir Martin Conway.

Mr. W. H. Wright, of the Lick Observatory, has been appointed George Darwin lecturer for 1928 of the Royal Astronomical Society. The lecture will be delivered in June, and will probably deal with the photography of the planets with different colour filters.

Sir Joseph Thomson will deliver the thirteenth Guthrie Lecture of the Physical Society, taking as his subject "Electrodeless Discharge through Gases." The lecture will be given on Friday, Mar. 9, at the Imperial College of Science and Technology, South Kensington, commencing at 5 o'clock. No tickets are required.

A provisional programme has been issued of the summer meeting of the Institution of Electrical Engineers, to be held in Norway on June 9-24. The meeting will take the form of a tour, including Bergen, Dale, Eide and Ulvik, Odda, Voss, Oslo, and Gothenburg, where power stations, nitrate and other works will be visited.

At the annual general meeting of the Quekett Microscopical Club on Feb. 4 the following were elected officers for the ensuing year: *President*, Dr. W. T. Calman; *Vice-Presidents*, Mr. C. D. Soar, Mr. D. J. Scourfield, Sir David Prain, Dr. C. Tierney; *Hon. Treasurer*, Mr. F. J. Perks; *Hon. Secretary*, Mr. W. S. Warton; *Hon. Reporter*, Mr. A. Morley Jones; *Hon. Librarian*, Mr. C. S. Todd; *Hon. Curator*, Mr. C. J. Sidwell; *Hon. Editor*, Mr. W. S. Warton.

The Society of Chemical Industry was first established at Merseyside, and an interesting account by Dr. A. Holt of the development of chemical industries in Liverpool and the neighbouring districts is contained in its *Transactions* dated Dec. 2. Rather more than one hundred years ago, this part of Great Britain was chiefly given over to agriculture, but with the provision of cheap transport facilities its character has changed, until now almost every industry in which chemistry plays a part, from metallurgy to the manufacture of artificial silk, is carried on there. A summary is given of the progress of each separate industry.

A new catalogue (No. 301) has just reached us from Messrs. W. Heffer and Sons, Ltd., Cambridge. It deals with nearly 2400 second-hand works on mathematics, physics, astronomy, chemistry, chemical technology, metallurgy, dictionaries, and books of reference. It can be obtained free upon application to the publishers.

Messrs. Dulau and Co., Ltd., announce the forthcoming publication by them of "Index Londinensis," containing illustrations of flowering plants, ferns, and fern allies, being an emended and enlarged edition, continued up to the end of the year 1920, of Pritzel's Alphabetical Register of representations of flowering plants and ferns. The work has been compiled by Dr. O. Stapf, and will comprise six volumes and be completed by 1930.

Applications are invited for the following appointments, on or before the dates mentioned:—A lecturer in mathematics at University College, Dundee—The Secretary and Registrar, The University, St. Andrews (Mar. 2). An assistant pathologist and research fellow in the pathological department of the Hospital for Sick Children, Great Ormond Street—The Secretary, Hospital for Sick Children, Great Ormond Street, W.C.1 (Mar. 5). Teachers of mathematics and of science at the new boys' secondary school, Heaton, Newcastle-upon-Tyne—The Director of Education, Education Office, Northumberland Road, Newcastle-upon-Tyne (Mar. 10). A biologist at the Dove Marine Laboratory, Cullercoats—The Registrar, Armstrong College, Newcastle-upon-Tyne (Mar. 17). A senior lecturer in physiology in the University of the Witwatersrand, Johannesburg—The Secretary, Office of the High Commissioner for the Union of South Africa, Trafalgar Square, W.C.2 (April 16). A lecturer in mathematics at the University College of Hull—The Secretary, University College, Hull. A whole-time worker in the research department of St. George's Hospital Medical School—The Dean, St. George's Hospital Medical School, Hyde Park Corner, S.W.1. A lecture assistant in physical chemistry in the University of Bristol—The Registrar, The University, Bristol.

Our Astronomical Column.

Has Sirius changed Colour?—Much has been written on this question in recent years. Prof. T. J. J. See, in a *Sondernummer* of vol. 229 of *Astr. Nach.*, collected a large amount of evidence from classical sources which certainly appeared on the face of it to establish that Sirius was ranked with orbs of undoubted redness like Antares. The *a priori* improbability of such a change in 2000 years is so great that most astronomers seek some way of escape from this conclusion. Sirius can be seen closer to the horizon than most stars, and in that position it is truly said that it "alters hue, and bickers into red and yellow." In Egypt especially, where the heliacal rising of Sirius was watched for as a sign of the rising of the Nile, it must often have been observed near the horizon.

E. Dittrich, in *Astr. Nach.*, No. 5542, examines an Assyrian tablet of the epoch 885 to 860 B.C., in which Sirius (Kaksidi) is described as "red as copper," and gives reasons for concluding that this refers to the time when Sirius rose at the beginning of the night, and that its rising at that time would be the occasion of special observations. He alludes to the fact that Sirius is now classed as a dwarf, though one of the brightest of the dwarfs; this increases the number of stages through which it must have passed since it was a red giant.

Analysis of Cepheid Variables.—W. Zessewitsch contributes a paper on this subject to *Astr. Nach.*, No. 5534. He notes that many of these variables show periodic changes both in their periods and in the form of the light-curves. These can be represented analytically by series of sine terms. He considers that a physical explanation is afforded by Jeans's suggestion that these stars have split into two orbs at a date that is recent (in the standards of cosmogony) and that the period of rotation is not equal to that of pulsation. The period of rotation would tend to lengthen owing to tidal friction; on the other hand, increasing density would shorten the period of pulsation. The two stars RW Draconis and XZ Cygni are mentioned as those that have been most carefully studied: the results, so far as they go at present, are considered to support Jeans's theory.

Periodic Variations in Terrestrial Magnetism.—In *Geofysiske Publikasjoner*, vol. 5, No. 3, K. F. Wasserfall discusses the presence of periodic variations in magnetic data obtained from the polar station at Gjøahavn, which was occupied by Amundsen from Nov. 1903 until June 1905. The geographical coordinates of this station, situated near the magnetic pole, are Lat. 68° 37′ N., and Long. 95° 55′ W. The data used in the discussion are daily means of horizontal force derived from photographic registers; temperature records for Gjøahavn and Oslo, and Wolfer's sunspot numbers for the same interval, are also used for comparative study. On analysis of the data, the author finds indications of various periods ranging from 3·3 days to 70 days. The distribution of sunspots in longitude is examined in some detail, and suggestions are offered to account for a relationship between the indicated periods in the magnetic and temperature records and the state of solar activity at the time. The results obtained from so very limited a series of observations are naturally open to much criticism in spite of the value of records from high latitude stations. The only consistent periods found in magnetic data which are of general acceptance as being related to the sun's activity are (1) the 11-year cycle of the sunspots and allied solar phenomena, and (2) a period of about 27½ days, which corresponds to the sun's synodic rotation as given by the sunspot latitudes.

Research Items.

THE MALTESE CART-RUTS.—In *Man* for February, Miss M. A. Murray discusses, with a number of illustrations, the possible origin and purpose of the so-called cart-ruts of Malta. These cart-ruts are disappearing, but a series of air photographs, to be the basis of a complete map, is now being prepared by Prof. Zammit and Commodore Clark Hall. As regards their origin, it is clear that they are not the well-known natural parallel fissures which occur in limestone, for they curve, and are equidistant throughout their length, the gauge being a little greater than that of a Maltese cart. The depth is not great, being about a foot. The Greeks appear to have cut similar ruts to facilitate the passage of carts over rough ground, but the curves for passing do not occur in Malta. There is a network of the ruts all over the island, and short lengths are frequent in connexion with megalithic monuments. This is an indication of age, which is also supported by the fact that they were made when the configuration of the island was different. One at St. George's Bay was evidently made across a gulley now covered by the sea, as it appears on both sides of the bay. Tracks also lead to the edge of cliffs, where they end abruptly. A tradition says that the tracks were made for a boat which went on wheels It is possible that they are part of a road system which was superseded by the Roman roads.

NEW DEEP SEA FISHES.—Among the collections of the third oceanographic expedition of the *Pawnee* were 32 specimens of the deep sea fishes of the sub-order Ceratioidea, which are described by Mr. A. E. Parr in the *Bulletin of the Bingham Oceanographic Collection*, vol. 3, Art. 1, August 1927. The collection was composed of eighteen species, eleven of which are regarded as new to science. So little is known of the developmental stages of these deep sea anglers that the author makes a point of recording a number of different body measurements for each specimen. The commonest species was *Melanocetus Murrayi* Günther, of which there were ten specimens, covering a wide range of size, the smallest being 17 mm. in total length, and the largest 115 mm. without the caudal fin. In the same series of publications, vol. 1, Art. 1, October 1927, Mr. C. M. Breder, Jr., records the results for fishes collected on the first expedition of the *Pawnee* in the West Indies by Mr. Harry Payne Bingham. The area from which the fish were taken includes the coastal regions of South Florida, Bahamas, Cuba, Grand Cayman, and British Honduras. Records for large numbers of different species are given, mostly shallow water and shore forms, and twenty new species are described. The most remarkable was a small eel-like fish named *Anguillicthys bahamensis* nov. gen., n. sp., by Mr. L. L. Mowbray, from whom the collections were taken over. This fish, about 4½ in. in length, differed from other eels in having a well-developed lunate caudal fin, the insertion of the anal and dorsal fins behind the vent, and their separation from the caudal fin by a long peduncle. The specimens were taken at the surface at night and were very rapid swimmers. They were considered to be eels that have taken to a mid-water life, and to lie between Anguilla and the type of true fishes. Both publications are well illustrated by Mr. W. S. Bronson, who is also executing a number of coloured paintings for the collection.

RESEARCH WORK AT PORT ERIN.—The forty-first Annual Report of the Marine Biological Station of Port Erin, Isle of Man, drawn up by the Director, Dr. Jas. Johnstone, professor of oceanography in the University of Liverpool, states that the work has been carried on along the usual lines during the year 1927, the equipment for general biological and chemical investigations having been improved and being now quite satisfactory. The pupils of Dr. Margery Knight have added much to the knowledge of the algæ of the district, and a series of memoirs have been written. Among these the researches by Miss E. M. Higgins on *Colpomenia sinuosa* are of peculiar interest, as this alga, formerly known from warmer seas, has since 1905 been found on the British coasts, and in 1916 was freely floating in the Irish Sea. As it affects oysters by clinging to their shells and then forms vesicles having sufficient buoyancy to lift away the whole mollusc, it is of considerable economic importance. The plaice in the hatching ponds continue to spawn, upwards of 4,000,000 larvæ having been set free from February to April, and also more than 4000 larval lobsters, besides 387 lobsterlings reared in the laboratory and liberated at suitable places along the coast. Research in the bio-chemical laboratory has been chiefly on the physical and chemical side, the Naturalist of the Marine Station, Mr. J. R. Bruce, having completed papers on "The Physical Factors on a Sandy Beach" which are about to be published.

ICE-DRIFTS AND SEAL-FISHING.—In a note on Dr. Iversen's paper "Drivis og Selfangst" in our issue of Jan. 14, p. 71, it was stated that "The Bladder-nosed seals . . . defend their young, keeping with them for a longer time" than the Greenland seal does. Dr. Iversen writes to correct this, as it is the period during which births are known to occur which is longer for the Bladder-nosed seal than for the Greenland seal, not the length of time the young is cared for. He says: "The drift ice at Jan Mayen is the breeding-place both for Greenland seal and Hooded seal at the end of March and in April. The Hooded seal is believed to give birth to its young at about the same time as the Greenland seal, the period being, however, somewhat more extended and the breeding area generally situated a little more to the south." Further, referring to the statement that whole families of Bladder-nosed seals are often shot down, he says, "It is, of course, not possible to say whether the small flocks met with really represent an actual family, wherefore I have placed the word in question (*familien*) between inverted commas Very little, as a matter of fact, is known about the habits of this species."

THE STORING OF EARTHWORMS BY MOLES.—In view of the fact that the most authoritative work on British mammals, by the late Major Barrett-Hamilton, throws grave doubt upon the reliability of the accounts of the deliberate storing of earthworms by moles, the experiments of M. Degerbøl deserve attention (*Vidensk. Medd. f. Dansk Naturh. Foren* , Bd. 84). He recounts the plain evidence previously furnished by Fr. Dahl and Ritzema Bos, and shows how, during his own experiments, the supply of superabundant food led to underground storing by a captive mole. As many as 49 large earthworms were stored in underground runs in 40 minutes, and the storing ceased only because the earthworm store was exhausted. Careful excavation of the runs showed that the worms had been pushed into holes formed in compressed earth in the walls of the burrows. In each hole a series of worms was placed, from a depth of about 4 inches to the surface of the run, but each worm was separated from its neighbours by a thin layer of packed earth. The worms were all alive, and except when the mole was flustered by too great *embarras de* *richesse*, the escape of the victims was provided against by the destruction of the first few head segments. The evidence of the experiments, as well as the evidence of other well-authenticated cases in natural conditions, suggests that the storing is not a provision against the appearance of dearth in hard weather, but is a direct reaction to over-abundant food supplies.

THE BREWING VALUES AND ANTISEPTIC POWERS OF HOPS.—In Great Britain the three principal methods for the analysis of hops in use at the present time are: a gravimetric method, Chapman's biological method (NATURE, 115, 244; 1925), and a method in which the amounts of lactic acid produced in a standard volume of malt wort by *Bacterium Delbruckii*, in the presence of varying quantities of a decoction of the hop, are determined by titration. The advantages of biological methods, the Chapman method in particular, include the speed with which they may be carried out, and the production of a result which depends on the actual antiseptic power of the hop. Gravimetric methods, on the other hand, though more readily standardised, depend on the extraction of the α- and β-resins by means of solvents and the grading of the hops in terms of an arbitrary factor connecting the two values obtained. The need for strict standardisation in the latter case is thus apparent, and papers by J. J. H. Hastings and T. K. Walker, and by A. H. Burgess and H. Martin (*Jour. Inst. Brew.*, 34, 9, 13; 1928) may be welcomed as a step in this direction. Both pairs of authors have come to the same main conclusion, namely, that to secure a more complete extraction of the β-resin, which is of brewing value, the methyl alcohol used must be diluted. An improved method is thence described in which the ether extract of the hop is re-extracted with the necessary amount of methyl alcohol, the α-resin precipitated by lead acetate, and the β-resins determined by difference from the total soft resin content. Unfortunately, in the past a close correlation between resin content, preservative value, and the results of small-scale experimental brews has not always been obtained, and it is hoped that the improved method may to some extent remedy this.

EUCALYPTS IN SCOTLAND.—A paper by Mr. J. A. B. Macdonald in the *Scottish Forestry Journal* for October last affords some interesting details of the growth of certain species of Eucalyptus which were planted out from thirty to thirty-three years ago at Kinlochourn, Inverness-shire, by the late Mr. R. Birbeck. The site is a steep sheltered slope, with a southern aspect; the rainfall varies from 90 to 140 inches per annum; and although the climate is generally mild, the sea loch is frozen over on very rare occasions. It was observed by Mr. Birbeck that the trees, when planted in a well-drained soil, enjoyed the high rainfall; the young trees, however, were tried severely by the Atlantic gales. *E. amygdalina*, *E. coriacea*, *E. regnans*, *E. rudis*, and *E. resinifera* suffered from the climate, and *E. globulus* was killed by fifteen or twenty degrees of frost. Specimens of *E. vernicosa*, *E. alpina*, *E. angustifolia*, *E. cordata*, and *E. viminalis* were flourishing in 1899 at the time of Mr. Birbeck's report; but of some fifty species originally planted out, the hardiest were *E. coccifera*, *E. Gunnii*, and *E. urnigera*. Three species have recently been identified and examined. A specimen of *E. cordata* measures 35 feet in height, with a girth of 81 inches; a specimen of *E. Muelleri* is 40 feet in height and 57 inches in girth. The commonest species is *E. coccifera*, which has attained a maximum height of 65 feet, with a girth of 45 inches. There are also other species in the area; all of them appear to fruit profusely, but no seedlings have been found. The members of a neighbouring group of birch trees of the same age vary from 20 to 35 feet in height, with an average girth of 25 inches, and the tallest trees in a group of Scots pines growing alongside are about 35 feet in height, with a girth of 32 inches. *E. coccifera* is one of the few endemic eucalypts of Tasmania, where it grows on or near the snow-line: it belongs to the 'peppermint' group, and yields an essential oil containing α-phellandrene and piperitone; like *E. Gunnii*—the 'cider gum' of Tasmania and the highlands of Victoria and New South Wales—it has no economic value as an oil-producing tree. *E. cordata*, *E. Muelleri*, and *E. urnigera* are Tasmanian species which yield a good type of oil containing cineole and pinene.

THE EFFECT OF HEAT ON COMMON HORNBLENDE.—The *Science Reports of the Tôhoku Imperial University*, Ser. 3, vol. 3, No. 2, Nov. 1927, contain a preliminary paper on the dissociation temperature of brown hornblende by S. Kôzu and B. Yoshiki, which is followed by a more detailed account (with the additional collaboration of K. Kani) of the transformation of common hornblende into the basaltic variety at 750° C. At this temperature the refractive indices and birefringences rapidly increase, and the extinction angles decrease to nearly zero on the prism face. The pleochroism also changes from various tints of green to brownish green into the characteristic reddish-brown shades of the basaltic type. The expansion on heating gradually increases to 750° C., and then changes suddenly to a contraction; at 790° expansion begins again. Natural basaltic hornblende shows none of these changes on being heated, but has from the start almost the same properties as those reached by ordinary hornblende beyond 750° C. The expansion curve shows no break until 1080° C. is reached, at which point there is great expansion accompanying the dissociation of the mineral. These results clearly have petrological implications of considerable importance.

BASALTS OF THE GALAPAGOS ISLANDS.—A paper by H. S. Washington and Mary G. Keyes in the *Jour. Wash. Acad. Sci.*, Dec. 19, 1927, contains an account, with chemical analyses, of some specimens collected on the islet of Eden. These are mainly palagonite tuffs and an olivine-andesine-basalt closely resembling a common Hawaiian type. The authors make no mention of the recent *St. George* Scientific Expedition (*Geol. Mag.*, 1925, p. 371) or of the collections of lavas then made by L. J. Chubb. Some of these, from Albemarle and James, have already been analysed by Raoult and described by Lacroix (*Mém. de l'Acad. des Sciences*, p. 69; 1927). Chubb's basalts are more basic than the one from Eden; they are respectively rich in bytownite and olivine. All the authors cited are agreed that there is close similarity between the Galapagos basalts and those of the Central Pacific. Lacroix points out the striking difference of the lavas from those of the andesitic types of the Circum-Pacific belt. Washington and Miss Keyes direct attention to the earlier observations of Gooch, which indicate the presence of trachyte and trachybasalt on some of the islands. It is clear, therefore, that the Galapagos Islands afford another example of the frequent oceanic association of common basalt with trachytic and melanocratic differentiates.

THE ABSORPTION SPECTRUM OF NITROGEN PEROXIDE.—The results of a careful investigation of the absorption spectrum of nitrogen peroxide are embodied in a dissertation by L. C. K. Carvile, presented to the Academic Faculty of the University of Virginia. The spectrum was photographed with a 21-ft. Rowland grating, but in consequence of the difficulty of maintaining constant temperature during the long exposures required, the average deviation from the mean for the same line on different plates amounted to 0·03A. This, however, is a great advance on any previous measurements, and the new determinations will provide a substantial basis for an investigation of the structure of this spectrum. About 6600 lines, covering the range λ3978 to λ6323, are included in the catalogue. No change in the positions of the lines could be detected when the temperature of the absorbing gas was raised from 4° to 26° C. Anyone interested may obtain a copy of the dissertation gratis on application to the Director of the Rouss Physical Laboratory, the University, Virginia, U.S.A.

Gaseous Bearings.—The issue of the *Journal de Physique* for November contains a communication from MM. E. Henriot and E. Huguenard on the use of gaseous bearings for small rotors and on the extremely high speeds of rotation which can be obtained in this way. The fixed part of the bearing is a vertical cone of semivertical angle about 60° and 1 cm. side. Half-way down the side there are 8 or 10 holes up which air or carbonic acid gas at 2 to 6 atmospheres pressure is forced. The rotary part is coned underneath, the semivertical angle being about 65°, and the conical surface is provided with fine grooves along its generating lines. With a rotor of 1 cm. diameter a speed of 11,000 revolutions per second was obtained, and with it the Foucault measurement of the speed of light could be made with the reflecting mirror only 1 m. away. Rotors of 2·5 kilograms have been driven at 1100 revolutions per second. In all cases it is found desirable to mount the fixed part of the bearing so that a little side play is possible.

Microscope Technique.—In the January issue of *Watson's Microscope Record*, T. Thorne Baker discusses the use of light filters for increasing contrast in photomicrography. Contrast filters should be complementary in colour either to the primary object or to the background. To get the best results a plate suitable to the composition of the contrast filter must be used. Ordinary plates are suitable for use with violet or blue filters; orthochromatic plates with green or yellowish-green filters; and panchromatic plates with orange, red, or deep red filters. A list is given of some common microscopic stains and the colours of the most suitable contrast filters for use with them. Various methods of preparing metal specimens for microscopical examination are described by W. Cartwright. The structure of the metal may be developed by polish attack instead of by etching. In this method the polishing process is carried on in the presence of a slightly corrosive liquid. The method of heat tinting is useful for the detection of small differences in concentration of solid solutions, whilst electrolytic etching is of value in special cases. The journal also contains articles on measurements with the microscope, and on the use of the microscope in the textile industries and in the paper industry.

A Novel Distillation Flask.—A novel type of distillation flask is described in the *Chemiker-Zeitung* of Dec. 21, which, it is claimed, possesses many advantages over the ordinary Claisen-flasks used in distilling liquids under reduced pressure. By means of a simple device, any liquid which may be carried forward mechanically with the vapour is separated from the latter and returned automatically to the main bulk of liquid. The apparatus is supplied by the firm of Emil Gundelach, Gehlberg, Thüringer Wald.

The Chlorination of Mustard Gas.—Although mustard gas (β, β-dichloroethyl sulphide) may be destroyed in small quantities by treatment with nitric acid or steam, the only practical methods for its removal involve the use of chlorine. Almost all the compounds theoretically possible on treating mustard gas with chlorine have been isolated by T. P. Dawson and W. E. Lawson, and an account of their properties is contained in two papers in the December number of the *Journal of the American Chemical Society*. All the chloro-derivatives below the hexa-compound are, with one exception, unstable, and on distillation form unsaturated compounds with evolution of hydrogen chloride. All the chlorination products of mustard gas are non-vesicant, that is, they do not cause blistering of the skin.

Studies on Inflammability of Hydrogen.—The influence of dimethyl selenide and telluride on the limits of inflammability of hydrogen–air mixtures has been investigated by Yoshio Tanaka and Yuzaburo Nagai, and their results are described in the *Journal of the Society of Chemical Industry of Japan* (vol. 30, No. 10). The addition of two molecular per cent. of dimethyl selenide caused the molecular per cent. of hydrogen to fall from 71 to 37·5 in the case of upper limit mixtures, while with the same amount of telluride the molecular per cent. of hydrogen was 40. Hydrogen selenide and dimethyl and diethyl selenides have the same theoretical flame propagation temperature, namely, 1750° C., but different amounts of each are required to raise the flame propagation temperature of hydrogen from its initial value of 1090° C. to 1750° C. This appears to be due to differences in the mean cross-sectional areas of the molecules of the selenides giving rise to different collision probabilities for the selenide molecules with the activated hydrogen molecules.

The Copper-oxide Rectifier.—At the National Radio Exhibition considerable interest was shown in a new and very efficient form of rectifier called the copper-oxide rectifier. The phenomenon on which the working of the device depends was described by Grondahl and Geiger in April 1926 to the American Physical Society. A full account of the construction and properties of actual rectifiers appeared in the *Jour. Amer. Inst. Elect. Eng.* for March last, and a brief account is given in *Experimental Wireless* for January 1928. Grondahl found that when a layer of oxide is formed on a sheet of copper and contact is made through a piece of lead pressed against the oxide, the resistance to an electric current passing from the lead to the copper is in certain cases very much less than when the current flows in the opposite direction. The action is analogous to a slightly leaky hydraulic valve, in which the water flows easily in one direction and scarcely at all in the other. For an applied pressure of four volts, the resistance in one direction is 12,000 times that in the other. In practice the rectifier consists of an oxidised copper disc against which a leaden ring is clamped. If properly designed for the output required, an efficiency of 80 per cent. can be obtained. The film of oxide is only about one-thousandth part of an inch thick, and no satisfactory theory has yet been given of the action of the valve. This type of rectifier has many advantages, from the engineering point of view, over the liquid types at present in use for rectification, as there is no liquid to spill or evaporate. There are also no moving parts. It is being made for many purposes. One form can be used for charging a six-volt battery at a two ampere rate. Another form can be used for charging the high tension batteries used in broadcasting.

Royal Society Election.

Selected Candidates.

THE president and council of the Royal Society have recommended the following candidates for election as fellows of the Society :

G. Anrep, M.D., D.Sc. Distinguished as a physiologist, especially for his work on conditioned reflexes, nature of the secretory process, physiology of digestion, and significance of adrenaline. Has during the last few years conducted a series of masterly researches on the central and reflex regulation of the heart and circulation, and of the blood supply to the heart muscle, based on the use of the innervated heart lung preparation, which was invented for this purpose.

H. Bateman, M.A., Ph.D. Professor of Mathematical Physics in the California Institute of Technology, Pasadena. Formerly Fellow of Trinity College, Cambridge. Introduced (*Proc. Lond. Math. Soc.*, 1909) into the relativity theory of the electromagnetic equations a general quadratic form whose coefficients are characteristic of the medium supporting the field—partial anticipation of general relativity. Discovered the integral equation by which seismic rays in the earth's interior were afterwards calculated by Knott (*Phil. Mag.*, 1910). Has greatly extended the theory of solutions of partial differential equations, especially those occurring in physics. Has published solutions, both analytical and numerical, of various types of integral equations ; also papers on radiation and geometry.

C. H. Browning, M.D., D.P.H. Professor of Bacteriology, University of Glasgow. Distinguished for his researches in bacteriology, immunity, and chemotherapy. Author of "Recent Methods in the Diagnosis and Treatment of Syphilis" (with J. Mackenzie, 1911); "Applied Bacteriology" (1918); "Chemotherapy in Trypanosome Infections" (*Jour. Path.*, 1908); a number of papers on an analysis of the Wassermann reaction, especially on the action of cholesterin and lecithin; "Isolation of Typhoid Bacilli by means of Brilliant Green" (*Jour. Hyg.*, 1913); "On Flavine and Brilliant Green" (*Brit. Med Jour.*, 1917); "Bactericidal Action of Ultra-violet Radiation" (*Proc. Roy. Soc.*, 1917, with S. Russ); "Bactericidal Properties conferred on the Blood by Diamino-Acridine Sulphate" (*ibid.*, 1918); papers on antiseptic action and chemical constitution (*ibid.*, 1922, 1924, jointly); and others.

Stanley S. Cook. Engineer. Since 1906, controlling calculation steam turbines for Parsons' Marine Steam Turbine Co., and licences all principal countries. On Sub-Committee of B.I.R., calculated pressures attained by collapsing water cavities, results independently confirmed by Lord Rayleigh. Calculated temperatures reached by compression of flame. Joint author of "Compressibility" (*Proc. Roy. Soc.*); "Erosion of Propellers" (*Inst. Naval Arch.*, 1919); "Mechanical Double Reduction Gears, investigating Torsional Vibration" (*ibid.*, 1921); "Mechanical Gearing, investigating Oil-quenched Nickel Steel Pinions" (*ibid.*, 1923). Roy. Soc. Arts, Howard Lectures, 1923.

W. D. Dye, D.Sc. (Lond.), A.C.G.I. Head of Electrical Standards and Measurements Section of the National Physical Laboratory. Has established accurate and permanent standards of capacity and inductance suitable for radio frequencies, and has developed a self-contained standard of radio frequencies of high accuracy embodying a tuning fork control. Member of the National Committee for Wireless Telegraphy and of the International Committee for Radio Standards and Measurements. An authority on electrical standard measurements and precision measurements and on the magnetic properties of materials. Publications: "Calculation of a Primary Standard of Mutual Inductance" (*Proc. Roy. Soc.*, A, **101**); "The Valve maintained Tuning Fork as a Precision Time Standard" (*ibid.*, A, **103**); "A Self-contained Standard Harmonic Wavemeter" (*Phil. Trans.*, A, **224**). Author of articles on magnetic measurements and on radio measurements in Glazebrook's "Dictionary of Physics"

C. C. Farr, D.Sc. Professor of Physics, Canterbury College, N.Z. Fellow and Hector Medallist, New Zealand Institute. Distinguished for his contributions to general physics. As Director of Christchurch Magnetic Observatory, he made a complete magnetic survey of New Zealand and outlying islands. The results were published by the New Zealand Government. Author of many papers including "Interpretation of Milne Seismograms" (*Phil. Mag.*, 1903); "Continuous Observations of Dissipation of Electric Charges in Open Air" (*Proc. Roy. Soc.*, 1905); "Radium Contents of Igneous Rocks from Sub-antarctic Islands of New Zealand," with D. C. Florance (*Phil. Mag.*, 1909); "The Viscosity of Sulphur," with D. B. Macleod (*Proc. Roy. Soc.*, 1920).

Major Greenwood, F.R.C.P. Has applied the statistical method to the elucidation of many problems of physiology, pathology, hygiene, and epidemiology. Is the author, or joint author, of more than sixty papers dealing with these applications, including important contributions to the experimental study of epidemiology (*Jour. Hyg.*, **24**, 1925, Greenwood and Topley, *ibid.*, **25**, 1926, Greenwood, Newbold, Topley, and Wilson). Has done much to encourage and develop the use of modern statistical methods by medical laboratory investigators, and, as chairman of the Medical Research Council's Statistical Committee, to secure the adequate planning and execution of field investigations.

J. W. H. Harrison, D.Sc. Lecturer in Zoology at University College (Armstrong College), Newcastle-on-Tyne. Distinguished for his original work in experimental zoology, demonstrating the non-Mendelian inheritance of specific characters and the breaking down of a Mendelian unit-character (melanism) in interspecific crosses in Lepidoptera; the induction of melanism in Lepidoptera by feeding larvæ on plants charged with metallic salts and its subsequent inheritance on a Mendelian basis; the inheritance of acquired egg-laying instincts in Hymenoptera and the importance of extraneous influence in the determination of sex. He has also studied the cytology of the varieties and hybrids of British roses and willows.

W. N. Haworth, D.Sc. (Manc.), Ph.D. (Gottingen). Professor of Chemistry in the University of Birmingham. Author or joint author of many memoirs, published chiefly in the *Journal of the Chemical Society*, on organic synthesis and on the constitution of some terpenes and carbohydrates. He had determined the structure of many of the di- and trisaccharides, including sucrose, maltose, lactose, melibiose, cellobiose, gentiobiose, raffinose, and gentiacrose, and has synthesised amygdalin.

D. Keilin, M.A. (Cantab.), D.Sc. (Paris). University Lecturer in Parasitology, Cambridge. Distinguished for his researches on (*a*) Insecta, their anatomy, biology, and physiology, (*b*) Protista, having made important contributions dealing with the life history of new parasitic forms; (*c*) Cellular respiration, having made a fundamental discovery in the intracellular pigment 'cytochrome' which is present in all organisms.

F. L. Kitchin, Sc.D. (Camb.), Ph.D. (Munich). Palæontologist to the Geological Survey of Great Britain. Distinguished for his researches in invertebrate palæontology, especially in its application to stratigraphical geology. Has elucidated the lower Cretaceous fauna of South Africa (*Annals S. African Museum*, 1908) and the Jurassic Brachiopoda and Lamellibranchia of India (*Palæontologia Indica*, 1900, 1903). Has thoroughly investigated the faunas and correlation of zones in the concealed Mesozoic rocks of the Weald (*Mem. Geol. Survey*, 1911, 1923); has investigated the zonal representation and relations of the Gault of England (*Geol. Mag.*, 1920, 1922). Author of many palæontological contributions to Geological Survey memoirs.

F. S. Macaulay. Distinguished for his contributions to the theory of modular systems. Author of "On the Resolution of a Firm Modular System into Primary Systems" (*Math. Ann.*, **74**, 1913); "The Algebraic Theory of Modular Systems" (Camb. Math. Tracts, No. 19, 1916); "The Resultant of a Number of Polynomial of the same Degree" (*Proc. Lond. Math. Soc.*, **21**, 1922); "Some Properties of Enumeration in the Theory of Modular Systems" (*ibid.*, **26**, 1927). Also of various papers on algebraic geometry.

S. B. Schryver, Ph.D., D.Sc. Professor of Biochemistry, Imperial College of Science and Technology. Distinguished for original investigation in chemistry, especially biochemistry. He has made valuable contribution to our knowledge of morphia alkaloids (*Trans. Chem. Soc.*, 1900); autolysis (*Jour. of Physiol.*, 1904); Aggregation in colloids, especially clotting (*Proc. Roy. Soc.*, 1910–16); "The Chemical Aspects of Proteins, especially Gelatine" (*Biochem. Jour.*, 1920, onwards). He has done valuable work in chemistry in relation to plant physiology, including studies of the nitrogenous metabolism of plants (*ibid.*, 1920), of pectic substances and hæmicelluloses (*ibid.*, 1918, onwards). In addition he has been the instigator of much other research work issuing from his laboratory. A series of papers has been published on the hydrolysis of proteins and on the discovery of hitherto unknown hydrolysis products of these substances.

W. Stiles, Sc.D. Professor of Botany, University of Reading. Distinguished for contributions to plant physiology. In his work on permeability he developed new methods, and his investigation of the equilibria concentrations of salts within and without the cell are of particular importance. He has made valuable contributions to knowledge of the action of cold on tissues, "The Preservation through Food by Freezing" (1922), and on "Diffusion through Gels." His books on the assimilation of plants (Jørgenson and Stiles), "Carbon Assimilation" (1917), and on "Cell Permeability" (1923), exhibit critical powers of a very high order and are of great value in the further development of research work in these fields.

R. Whytlaw-Gray. Professor of Chemistry, University of Leeds. Distinguished for his researches in physical and inorganic chemistry, especially in the application of the determinations of the densities and combining volumes of gases to the atomic weights of the constituent elements. Was the first to correct Stas' atomic weight of nitrogen. With Sir William Ramsay determined the density of radium emanation and the atomic weight of radium. With collaborators carried out various researches on the compressibilities and limiting densities of various gases. Determined the critical constants and orthobaric densities of xenon. Has carried out extensive researches for the Chemical Warfare Department on the behaviour of clouds and smokes.

The Gold Coast Forests.

An important monograph has been drawn up recently by Dr. T. F. Chipp, entitled the "Gold Coast Forests: a study in Synecology" (Oxford Forest Memoirs, No. 7, 1927). In the introduction it is pointed out that no purely ecological study of the Gold Coast forests has been recorded, and that such a study has been impossible so long as the component units forming the structure of this mass of tropical vegetation have remained undetermined and uninvestigated. Considerable progress has been made in the floristic study of this forest area, as evidenced in the gradual expansion of the enumeration of the flora in the successive volumes of the "Flora of Tropical Africa," a work commenced in 1868 and only now approaching completion. A similar advance has also been made in the study of the plant distribution, and Engler's comprehensive survey in "Die Vegetation der Erde" (1908–10) is passing out of date.

The study of economic botany has made rapid progress with the establishment and expansion of the Agricultural and Forestry Departments. This progress is also depicted by such publications as "The Useful Plants of Nigeria" (*Kew Bull.*, Ad. Ser. 9) which includes the economic plants of the Gold Coast. Climatology has also recently received considerable attention. Apart from ecology, the area covered by the forest mass has been definitely determined, the chief physiognomic types of the forest have been recognised, and variations corresponding to the chief changes in climatic and edaphic factors have been recorded. Thompson's "Report on Forests: Gold Coast" (1910) recognises certain serial stages, plants, and communities of indicator value, and discusses the reaction of the population to the forest; he also adds lists of species occurring in different parts of the forest. Dr. August Chevalier in "Les végétaux utiles de l'Afrique tropicale française" has enabled the Gold Coast Forest, as a whole, to be viewed in its right perspective in relation to the rest of the vegetation in West Africa. During the War, A. Bertin, Conservateur des Eaux et Forêts, travelled extensively in some of the forest areas in the French possessions in this region, and published descriptions of the trees and their economic uses in five volumes, "Mission forestière coloniale," of high interest. As an outcome, soon after the termination of the War, Bertin was entrusted with the formation of a forest department to have charge of these areas. At the International Forestry Congress held at Rome in May 1926, Bertin read a paper on these forests, having for its object the placing of some of their timbers on the Italian market, Italy importing a considerable proportion of her annual timber requirements.

As Dr. Chipp points out, and the remark applies equally to several of our other Colonies and Protectorates. In a new country like the Gold Coast, where agriculture and forest exploitation have only assumed importance during the present generation, the tendency has been to concentrate all study and investigation on these, for they alone have an immediate economic bearing. In the meantime, the natural covering, a knowledge of the stages in development of which may prove of great economic importance to the inhabitants, is rapidly disappearing. The value of a study, in time, of the indicator communities and individuals may prove of equal importance from the protective point of view; such a study will indicate the parts of a country which it is vital to keep afforested. For example, in the case here considered, to check the oncoming effects from the desert to the north, to ascertain over what areas forest will naturally replace destructive forest exploitation, the protection required in the catchment areas of the rivers and springs of the country, and whether hill systems or isolated peaks may be deforested with impunity. Dr. Chipp well sums up the case as to the importance of such investigations in the following:

"The value of the economic interpretations resulting from such a study cannot be over-estimated in the case of a country almost entirely dependent on the character and maintenance of its vegetation, not only for its material wealth, but ultimately for the very existence of its inhabitants. A narrow strip of country abounding in natural and easily exploitable wealth and actually 'sandwiched' between an ever-encroaching desert and the sea, is literally dependent on scientific management to retain its existence. Such management must of necessity be based on studies such as the present, carried out in the field and worked out in the light of a knowledge of similar problems that have been encountered elsewhere."

Dr. Chipp therefore set himself the task of studying the forest-mass from the point of view of the basic units of which it was composed, their characteristics, the factors controlling them, and the scheme by which they joined together to constitute the whole. This, as he says, is where the present work breaks ground. It is impossible, within a limited space, to consider at any length the results achieved, but it may be stated that Dr. Chipp has carried out his object in a most painstaking manner, and it may be hoped that the valuable monograph, of value alike to the forester and the ecologist, is but the forerunner of others undertaken for other parts of the Empire. The work is illustrated with a number of interesting photographs, charts, and plans which serve to interpret the text in the clearest fashion.

University and Educational Intelligence.

CAMBRIDGE.—A very important development is indicated in a report of the Council recommending the institution of a library building fund. The need to move the University Library to a fresh site, where it would have room to grow up to its present needs, while keeping an eye on the future, has been urgently before the University for some years, but the sum of £500.000 required for the complete scheme has seemed prohibitive The Council has, however, found ways and means to finance a scheme of half that amount, and that would enable a substantial part of the new library to be erected. A recent bequest of £65,000 and other available monies are all to be devoted to this one purpose, and a recent increase in the University income under the new statute is in large part also to be assigned to the Library.

The Gordon Wigan prize in chemistry has been divided between A. Caress, Trinity Hall, for an investigation on "The Chemical Reactions of Atoms and Molecules Activated by Electron Collisions," and F. F. P. Smith, Peterhouse, for an investigation on "Studies in Chemical Reactivity."

Mr. J. E. Littlewood, F R.S., fellow and lecturer in mathematics, Trinity College, has been appointed to the newly established Rouse Ball chair of mathematics.

LONDON —A course of three free public lectures on "Heredity" will be delivered at Birkbeck College on Feb. 29, Mar. 7 and 9, at 5.30, by Dr. F. A. E. Crew, of the Animal Breeding Research Station, Edinburgh.

ST. ANDREWS.—At a meeting of the University Court on Feb. 17, a resolution was adopted recording the "deep sense of sorrow and loss" occasioned by the death on Jan. 29 of Field-Marshal the Earl Haig of Bemersyde, Chancellor of the University for the past six years.

AN election to Beit fellowships for scientific research will take place in July next. Forms of application and all information concerning the fellowships may be obtained by letter addressed to the Rector, Imperial College of Science and Technology, South Kensington, S.W.7. The latest date for the return of application forms is April 20.

PROF. J. H. DIBLE, professor of pathology in the University of London and honorary pathologist to the Royal Free Hospital, has been appointed to the chair of pathology in the Welsh National School of Medicine (University College, Cardiff). in succession to Prof. E H. Kettle. Prof. Dible previously held pathological appointments in the Universities of Sheffield and Manchester.

DR. LARS G. ROMELL, of the Swedish Forest Experiment Station at Stockholm, has been appointed to the Charles Lathrop Pack research professorship in forest soils at Cornell University. The establishment of this professorship, the first of its kind in an American university, has been made possible by the endowment of 130,000 dollars for the chair, together with important additional gifts for its operating funds, from the Charles Lathrop Pack Forestry Trust, founded by Charles Lathrop Pack, of Lakewood, N.J., president and founder of the American Tree Association. The new investigation will co-ordinate studies in several fields of science, and apply all the obtainable and applicable knowledge to the special problems of forest soils. Dr. Romell studied at the University of Stockholm, and has done special work in botany at the University of Strasbourg under Prof Jost, and in botany and cytology at the University of Lund under Prof. Lundegardh: he has also worked on the bacteriology of soils with Dr. Winogradsky near Paris. Since 1918 he has held an appointment at the Swedish Forest Experiment Station, in association with Dr. H. Hesselman, dealing with forest soils. The results of this pioneer work in America will be watched with interest by those concerned in the conservation of wood supply.

THE International Federation of University Women has published a report of its eleventh council meeting held at Vienna last July. At the opening, semi-public, session, Madame Puech, of the French Association, pleaded for a united effort against the exaggerated spirit of nationalism. In former times men of science and letters were to some extent supernational, but the modern, general, and democratic educational systems tend to foster a spirit which, far from "making the world safe for democracy," creates a feeling in the nationals of each country that it is entitled to a proprietary right in those intellects whose work should be regarded as the common property of humanity, and intellectual workers are thus tempted to adopt an antagonistic attitude towards other nations. To this the Federation can and does oppose its ideal of the open and friendly forum for university women of all countries. Reports from national associations of the United States, Austria, Belgium, Bulgaria, Canada, Czecho-Slovakia, Denmark, Estonia, Finland, France, Germany, Great Britain, Holland, Hungary, Ireland, Italy, Norway, Poland, Rumania, South Africa, Spain, Sweden, and Switzerland, show that all are actively engaged in promoting this ideal. The Federation is financed, however, mainly from America, whence came, last year, nine-tenths of the gifts and subscriptions. The headquarters of the Federation have been transferred from Victoria Street to Crosby Hall, Cheyne Walk, London, S.W.3.

Calendar of Customs and Festivals.

February 26.

First Sunday in Lent.—Known in Ireland as Chalk Sunday. It was customary for a great number of marriages to be celebrated in Ireland on Shrove Tuesday as the last opportunity before Lent. On the following Sunday, the girls surreptitiously chalked the coats of eligible young men who had not availed themselves of the occasion, thus exposing them to ridicule.

February 27.

Scambling Days.—The Mondays and Saturdays in Lent were known as Scambling Days. On these days no regular meals were provided and the members of the great households 'scambled,' *i.e.* made their meals off food obtained as best they could.

Feb. 27 is assigned as the day of several saints, of whom not unnoteworthy is St. Thalilæus of Syria, who "wept almost without intermission for sixty years and for ten years lived in a cage."

March 1.

St. David's Day.—St. David, Archbishop of Menevia, afterwards called St. David's. This saint flourished in the fifth and sixth centuries and is reputed to have died at the age of 146 years. He is said to have been of royal extraction but illegitimate, his father being one of the Welsh princes, his mother Non, daughter of Ynyr of Caer Gawch. In another account he is stated to have been an uncle of King Arthur—a matter of interest in view of the association of St. David with Glastonbury, where he founded a monastery, and to which place, it was said, his relics were translated in the tenth century.

St. David took a prominent part in the synod for the suppression of the Pelagian heresy held at Brevy in Cardiganshire. On this occasion he restored a child to life, and the ground whereon he stood to preach rose under him until it became a hill. When, after this synod, he designed to repair to his Glastonbury Monastery, he was forbidden by Our Lord in a vision, who with his finger pierced a hole in the saint's hand which remained open until the next day. St. David is also said to have been responsible for the heat of the waters of Bath, which he "cured of an infection." Many centuries after his death, in the reign of King Stephen, he caused the brook in the churchyard of St. David's to flow with wine, and the well near by to send forth milk instead of water.

St. David's Day, as that of the national saint of Wales, was at one time observed in the Principality with much festivity in rural areas. The wearing of the leek was general. It was the occasion for the exercise of a number of primitive beliefs. For example, the churchyards were visited at night to watch for corpse candles. The families on whose graves these appeared would, it was believed, lose a member within the next twelve months. A shoe thrown over the head indicated by the direction in which its toe pointed whether the thrower would move from that house or die within the year. If anyone walked round the bed of leeks three times in silence on St. David's Eve, he or she would see future wife or husband as the case might be.

The great feature in the observance of a saint's day in Wales, especially a local patron saint, was the Mabsant-revels which were celebrated up to so late as 1840 or 1850, and corresponded to the Irish Pattern and Breton Pardon. Their celebration on St. David's Day was, of course, general and not restricted to one locality. Religious services and processions were followed by feasting and dancing in the village inn.

It is clear that popular tradition has associated with St. David something over and above the miraculous element found in the lives of most early saints. This is shown, for example, by the Mabsant and in his reputed relationship to King Arthur. The wearing of the leek is linked with St. David, yet it is probable that the custom is much older. The traditional account is that it commemorates a battle in which the Saxons were defeated by the Welsh, who, at the instigation of St. David, wore the leek as a distinguishing badge. Another explanation is that the leek was worn to perpetuate the memory of David's abstinence in subsisting on this and other roots of the ground for many years.

It has been suggested that the veneration for the leek arose from its use by the Druids as a symbol. Possibly, however, it is connected with the custom of *cymhortha*, when farmers joined together to plough their lands in co-operation. It is said that each farmer had to provide a portion of leeks to make up the common meal. The closely interrelated interests of a small community with lands partly in common made it desirable that agricultural operations should be carried out more or less simultaneously, while for the heavier work, co-operation was essential. This can still be seen in remoter parts where one great plough, which can be drawn only by a large number of horses, has to serve the needs of all the farms of a district. The leek thus becomes a symbol of the vegetation to spring from this communal activity at the beginning of March, of which the termination was marked by a feast—the Mabsant. The saying, "On St. David's Day put oats and barley in the clay," may be an indication of some such communal activity as well as a mnemonic. The custom in London of burning a Welshman in effigy, to which Pepys refers in 1667, and of hanging up 'Taffies' or Welshmen of ginger-bread for sale on St. David's Day, may be a topical adaptation of the traditional lay figure of the spring observances to which reference has been made previously.

March 2.

St. Chad. A.D. 673.—Founder and bishop of the See of Lichfield. One of the numerous holy wells of London was dedicated to St. Chad. This was situated near Battle Bridge, and was still frequented for its medicinal virtues in the late eighteenth and early nineteenth centuries.

Friday in Lide, from *Lide*, A.S. March. In Cornwall on the first Friday in March, so called, a young lad was sent to the top of a mound or hillock and allowed to sleep there as long as he could, the length of his sleep fixing the duration of the tinners' midday rest for the next twelve months.

March 3.

St. Winnold.—St. Winwaloe, son of Fragan, who was nearly related to a prince of Wales, and took part in the Welsh migration to Armorica on account of the Saxon invasions. He gave his name to Plou-Fragan. Winwaloe founded a monastery at Landevinech near Brest, and, with other members of his family, is prominent in the hagiology of Brittany.

A priory in the Parish of Wereham, Norfolk, was dedicated to St. Winnold by the family of Clare at some date before 1206. Associated with it was Winnold's Fair for horses and cattle, at one time the largest and the oldest of the fairs in England. The name was retained though the fair was moved twice, first to Wimbolsham and then to Downham, after the Dissolution.

Societies and Academies.

London.

Royal Society, Feb. 16.—**A. Fowler** and **E. W. H. Selwyn**: The arc spectrum of carbon. Further observations of the arc spectrum of carbon (C I) have been made, and the classification of the lines has been considerably extended. The deepest term is a triplet P_0, the value of which is estimated as 90107, corresponding to an ionisation potential of 11·2 volts.

R. H. Fowler: The chemical constant of hydrogen vapour and the failure of Nernst's heat theorem. Dennison's theory of the specific heat of hydrogen requires that at ordinary and low temperatures it should behave as a non-combining mixture of two different sorts of molecules, the symmetrical and the antisymmetrical, in the proportion 1 to 3. It follows that the observed constant in the vapour pressure equation will be given only if liquid and solid hydrogen are equally mixtures of the two non-combining molecules in the same proportion. It then follows that the weight of the lowest state of solid hydrogen cannot have the value 1, so that the entropy of the solid remains positive at the absolute zero.

A. H. Wilson: The ionised hydrogen molecule. Schrodinger's method is applied to the quantisation of a molecular system consisting of one electron and two protons. If wave functions which are bounded in the whole of three dimensional space are used, the system admits of no stationary states. By employing a wave function which becomes infinite at the two nuclei and along the line joining them, stationary states exist for all distances apart of the nuclei. Formulæ are given for the calculation of the energy of the lowest state, and the minimum value of this for different nuclear separations gives the energy of the ion H_2^+.

A. H. Wilson: A generalised spheroidal wave equation. The equation is a second-order differential equation with three real singular points, two regular and the third irregular. It contains three independent parameters, and there are many types of solutions, but only two are of importance. The first class consists of those functions which are bounded in the real interval joining the two regular singularities. To obtain these functions it is necessary to impose one relation on the parameters. The second class of functions consists of those bounded in the real interval joining a regular singularity to the irregular point, and two algebraic relations must be imposed on the three parameters.

O. H. Walters and **S. Barratt**: The alkaline earth halide spectra and their origin. A method has been found by which the alkaline earth halide spectra can all be observed in absorption. The conditions of experiment prove that the spectra originate from subhalide molecules, probably of the type MX, and not from the normal salts. These subhalides exist in stable equilibrium with the metal and the normal salt as vapours at 1000° C. The spectra have been examined by the absorption method, and new band groups have been observed in the ultra-violet. The calcium fluoride band 5292 has been examined under high dispersion. Its structures, in absorption and emission, have proved to be very different.

T. R. Merton: On a new effect in the electric discharge. A new type of electric discharge has been observed in vacuum tubes containing helium and carbon. The principal feature consists in the formation of bright discs which, unlike the striæ usually observed in vacuum tubes, are unaffected by weak magnetic fields. A violent disturbance, such as the passage of a condensed discharge, is necessary to start the formation of the discs, which can only be maintained with alternating currents. When a direct current is superposed on the alternating current the disc moves towards the anode. When the tubes are excited by direct current there is a migration of carbon compounds to the cathode. The phenomena have been investigated by stroboscopic methods. Carbon monoxide is decomposed in the discs with the formation of a particulate cloud of carbon. The effects are discussed in relation to the phenomenon known as ball lightning.

P. A. M. Dirac: The quantum theory of the electron (Part 2). Proof is given of the conservation theorem, and further developments are made in the application to spectra of atoms with single electrons. The various series of terms are described by a single quantum number j, taking both positive and negative integral values. The selection rule for j is equivalent to the two selection rules of the previous theory. Relative intensities of lines of a multiplet, and the anomalous Zeeman effect for weak and strong fields, also give results in agreement with previous theories.

S. W. Watson and **M. C. Henderson**: The heating effects of thorium and radium products. A resistance thermometer method was employed, the calorimeter wall having an absorbing thickness equivalent to 0·7 mm. of aluminium. Using the known rate of emission of particles by thorium C relative to radium C, the ratio of observed to calculated heating is constant within experimental error for all five products, and agrees well with Hess and Lawson's value of Z, namely, $3·72 \times 10^{10}$ α-particles per gm. per sec. The discrepancy in the worst case, namely, thorium (B + C), is 2 per cent. If Geiger and Werner's value of Z, namely, $3·40 \times 10^{10}$, be correct, the excess heat over and above that provided by the known radiations must be a nearly constant fraction of the whole (9 to 12 per cent.) for all the substances investigated. It must also be in a form easily absorbed by 0·7 mm. of aluminium, and if electromagnetic would require about 40 quanta at least per atom disintegrating.

H. F. Baker: Note on the paper "Commutative Ordinary Differential Operators" by J. L. Burchnell and T. W. Chaundy. In the classical theory of Abelian functions, the passage from the algebraic functions to the theta functions is made by a function which is the exponential of a sum of integrals of the third kind; the upper limits of these depend on arguments determined by an inversion theorem. Messrs. Burchnell and Chaundy's paper deals with the particular case of this when all these arguments except one are zero. They use an extended inversion theorem which disguises the essential character of the coefficients in the differential equations obtained. Simplification is possible in the modular expression of algebraic integrals when the fundamental algebraic equation has the canonical Weierstrass form.

L. S. Ornstein, **W. Kapuscinski**, and **J. G. Eymers**: Intensity measurements in the secondary spectrum of hydrogen. The intensities of the lines in the secondary spectrum of hydrogen have been measured in the region 4500-4900 A. by the Utrecht method.

Optical Society, Jan. 19.—**T. Smith**: (1) On toric lenses. A system of toric lenses having a common normal to all their surfaces possesses in general ten independent primordial coefficients. A single surface has only three degrees of freedom, and this number also holds for any system of negligible axial depth. Formulæ are given for the calculation of the ten coefficients, which are only all independent when the system includes at least three separated toric refracting surfaces with their planes of principal curvature finitely inclined to one another. An eye with both its cornea and its crystalline lens astigmatic and the meridians of principal curvature different has more independent coefficients than a spectacle lens has effective degrees of freedom. (2) Canonical forms in the theory of asymmetrical optical systems. Canonical forms for the quadratic terms of the eikonal and of the characteristic function for any optical instrument involve only six arbitrary constants. The seven constant canonical form of the characteristic function obtained by Larmor is not general. Larmor's theorem on the equivalence of any optical system to a symmetrical instrument together with two thin astigmatic lenses also fails. Three separated astigmatic lenses are needed to represent the general system.—**M. Herzberger**: Some remarks on an extension of the optical cosine law. In this note reference is made to an extension of the optical cosine law, a full description of which will appear in the *Zeitschrift für Physik*.

Physical Society, Jan. 27.—**W. E. Pretty**: The Swan band spectrum of carbon. The Swan spectrum has been obtained in carbon monoxide and in the carbon spark in the absence of hydrogen. A discussion of the results of experiment and theory leads to the conclusion that the emitter of the Swan band system is the molecule of carbon (C_2).—**T. Smith**: On some misapplications of the law of errors and on the intrinsic error in focometry. In some physical measurements the uncertainty due to a single cause is not infinitesimal, and the precision of the mean of a large number of observations given by the law of errors is not then physically significant. An example is afforded in attempts to identify the position of an optical image. According to geometrical optics, this lies in a definite surface; but, owing to the physical properties of light, this surface cannot be identified experimentally. The use of a double cylindrical lens as a means of limiting more narrowly the space in which this surface lies is discussed.—**A. H. Davis**: Some acoustical phenomena illustrated by ripples—transmission through Quincke filters, curved conduits and vibrating partitions. The paper employs ripple photographs to illustrate the action of the Quincke acoustical filter, and directs attention to the filtering action which is likely to occur at bends in curved sound conduits or in curved horns owing to resonant transverse vibration of the contained air. It also illustrates by the ripple analogy the transmission of sound through partitions.

Edinburgh.

Royal Society, Jan. 9.—**Penelope M. Jenkin**: Note on the sympathetic nervous system of *Lepidosiren paradoxa*. A slender sympathetic trunk without obvious ganglionic swellings runs along each side of the dorsal aorta, receiving a *ramus communicans* from each spinal nerve throughout the length of the splanchnocœle. The trunk could be traced for a short distance into the tail region; anteriorly it could not be traced farther forwards than the first spinal nerve. Ganglion cells were found diffusely scattered through the trunk. No communication with the vagus ganglion, no collateral trunk, no medullated fibres, could be detected. On the whole, the sympathetic of Lepidosiren shows most close affinity to that of *Salamandrine urodeles*.—**D. Noël Paton**: Reflex postural adjustments of balance in the duck. A series of reflexes in the intact and in the decerebrated duck induced by disturbing the balance round antero-posterior and a transverse axes are described and analysed and explained as developed for the readjustment of equilibrium.—**E. A. Baker**: The law of blackening of the photographic plate at low densities (3). The dependence of the density of a photographic deposit on the conditions of exposure and development, in particular when the density is low, is interpreted as indicating that several distinct latent images are formed, the most important being a slowly developing image involving two consecutive quantum absorptions; a rapidly developing image involving three absorptions, together with an intervening 'emission' and a very slowly developing 'reversed' image involving three consecutive absorptions. Various phenomena, including those involving two separated exposures, are successfully predicted.—**Edith Philip Smith**: A comparative study of the stem structure of the genus Clematis, with special reference to anatomical changes induced by vegetative propagation. The genus includes 160 species, of cosmopolitan distribution, ranging in habit from lianes to woody herbs. Of these, 137 were examined. The general vascular anatomy of the genus is remarkably consistent, centring round the simple Vitalba-type with 12 foliar bundles. The origin of callus is from the interfascicular cambium: adventitious roots come from the fascicular cambium. Propagation by stem cuttings is made easier by previous partial etiolation: the anatomical effects of this treatment are discussed.

Paris.

Academy of Sciences, Jan. 16.—**Pierre Termier**: The *pays de nappes* of the French Alps.—**E. Leclainche** and **H. Vallée**: Vaccination against anthrax. A description of improved methods of preparing immunising sera from *Clostridium Chauvæi*. Filtration has been abandoned for supercentrifugation with subsequent addition of formaldehyde, and a mixed culture of various strains and different ages is used. Details are given of the results of the practical application of the sera, which is shown to be safe and effective.—**Nemours-Auguste** and **A. R. Barrieu**: The treatment of angina pectoris by radiotherapy.—**G. Nicoladzé**: An arithmometer with purely electrical direct multiplication.—**d'Ocagne**: Remarks on the preceding communication.—**Charles Colombi**: The number of specific turns of steam turbines.—**Emile Merlin**: Fluids with cylindrical stratification in rotation round an axis.—**Jean Fieux**: A new gyroscopic apparatus for preventing rolling of vessels. A description and drawing of the proposed apparatus is given, together with a curve showing the result of applying the apparatus to a vessel of 880 tons displacement.—**A. Lévêque**: The difference of the variation of temperature along the surface of exchange on the transmission of heat between this surface and a fluid in motion.—**A. Lafay**: The electromotive force of friction of metals. Subject to certain precautions described, it has been proved experimentally that the E.M.F. produced by the friction of metals is proportional to the relative velocities of the rubbing substances, and is independent of the pressure maintaining them in contact.—**H. Jedrzejowski**: The phenomenon of inversion in biotite submitted to the action of the α-rays. Joly, in discussing the explanation of the ring structure of the haloes in biotite, has suggested an inversion analogous with that shown by over-exposed photographic plates as the cause. This view is confirmed experimentally, and it is proved that in consequence the determination of the age of minerals by the haloes may lead to erroneous conclusions.—**Frilley**: Spectrography of the γ-rays by crystalline diffraction. The apparatus, described in detail, furnishes a parallel bundle of γ-rays, freed from β-rays, and the spectrum is obtained by the rotating crystal method (rock salt).

The lines attributable to radium *B* and radium *C* are comprised between 35 and 284 U.X.—**Georges Simon**: The development of a Daguerre plate by cathode pulverisation.—**Henri Chrétien**: Photographic method with high luminosity.—**H. Colin** and **Mlle. A. Chaudun**: Velocity of hydrolysis and hydrogen ion concentration. The results of experiments on the hydrolysis of sugar are given, in which the effect of various acids and addition of salts were studied: it was found that the variations of the hydrolysis constant are never parallel with the variations in hydrogen ion concentration.—**Pierre Chevenard** and **Albert Portevin**: Causes of the variation of volume accompanying the hardening of the light aluminium-copper alloys.—**P. Laffitte** and **P. Dumanois**: The velocity of the explosive wave. The velocities of the explosive wave in mixtures of hydrogen and oxygen and methane with oxygen, at varying initial pressures, have been measured by the photographic method both with and without added lead tetraethyl. The velocity of propagation of the explosive wave proved to be independent of the presence of the antidetonant in the gaseous mixture. —**Max** and **Michel Polonovski**: ψ-scopine and scopoline.—**E. Tassilly**, **A. Belot**, and **M. Descombes**: The saponification of ethyl phenylethylmalonate by alkalis. In this saponification, some phenylethylacetic acid is always formed, this forming the main product of the saponification in hot alcoholic solution.—**J. Bougault** and **L. Daniel**: The sulphoxytriazines.—**A. Apard**: The metallic complexes of the cellulose nitrates.—**Jacques Bourcart** and **M. E. Denaeyer**: The lithological characters of the intrusive rocks of the Central Sahara Massif (Jacques Bourcart expedition, 1922-1923).—**Paul Fallot**: The central part of the Sierras of Segura (Andalusia).—**F. Bordas** and **A. Desfemmes**: Rains containing dust and salt.—**A. Guilliermond**: Some new facts relative to the development of *Spermophthora gossypii*.—**P. Gavaudan**: The relations between the vacuome and the oil-bearing system of the Jungermanniaceæ.—**J. Amar**: The respiratory quotient.—**A. Fessard**, **H. Laugier**, and **S. Nouel**: The recovery index of a neuro-muscular system in the course of work.—**Philippe Fabre**: The form of the muscular contractions in indirect stimulation by linear currents.—**J. M. Le Goff**: The vasodilative action of the salts of cobalt.—**C. Dawydoff**: Some observations on the development of the Enteropneusts.—**L. Léger** and **C. Motas**: The lacustral fauna of the Grand Lautien.—**C. Mathis**: The experimental transmission of the spirochæte of the shrew mouse by the louse.—**Cordier**, **Lesbouyries**, and **Verge**: Hypoglycæmic syndrome and vitular fever.—**Marcel Labbé**, **H. Roubeau**, and **F. Nepveux**: The action of nickel and cobalt salts on the hypoglycæmic power of insulin in diabetes. —**Léon Blum** and **P. Grabar**: The alterations in the renal function by hypochlorination. An account of changes in the renal secretions, simulating nephritis of toxic origin, due to a deficiency of sodium chloride. —**Jean Saidman**: The therapeutic properties of X-rays of wave-length 8 A.

ROME.

Royal National Academy of the Lincei. Communications received during the vacation, 1927.—**U. Cisotti**: Spiral vortices.—**E. Bompiani**: Darboux quadratics and projective normal in a point of a surface.—**C. Rosati**: Riemann matrices.—**S. Cherubino**: Notions of parity and the real character of real Abelian varieties (1). Subnormal Riemannian matrices.—**G. Vitali**: A covariant derivation in generalised absolute calculus.—**Francesco Sbrana**: Theorems of the mean for the solutions of certain equations with partial derivatives.—**B. Finzi**: Biharmonic functions on a surface.—**A. Terracini**: Differential projective geometry of hyper surfaces.—**A. Masotti**: Observations on the motions of a fluid in which the distribution of the vortex is stationary.—**F. Ruda**: Explanation of the green ray. The variations in the colour of the last rays of the setting sun from green to blue may be attributed to the variable dimensions of the corpuscles held in suspension in the atmosphere, especially in the lower layers near to the earth's surface. When the absorption is very intense, the green or blue ray is naturally not seen, this being the case when the sun is red. Various factors may intervene to cause the divergence, at times considerable, between the theoretical and the actual durations of the phenomenon.—**C. G. Fontana**: Gold purple (2). Substances analogous to purple of Cassius may be obtained without the use of a stannous salt, the hydroxide of aluminium, zirconium, or thorium being utilised as a supporting material. In such cases the preparation is effected by means of a red, alkaline gold sol. The structure of aluminium gold purple and zirconium gold purple are completely analogous to that of purple of Cassius, the gold being present in the elementary condition and with the same high degree of dispersion. No such conclusion is found possible with the thorium gold purple.—**A. Desio**: The presence of the Miocene in the neighbourhood of El-Abiàr (Cyrenaica).—**S. Ranzi**: Differential inhibition in the development of cephalopods and considerations on the so-called axial gradient. The phenomena which, in embryos, seem to indicate the presence of an axial gradient, have their *raison d'être* in the special manner of development of the forms in question. The so-called axial gradient is not a regulator of the development, but a resultant, more apparent than real, of the occurrent phenomena, which in all cases diverge widely from Child's scheme of one or two dominant points (at the cephalic and caudal extremities).—**D. Cattaneo**: Ultramicroscopic investigations on the crystalline lens (3). Modifications of the ultramicroscopic structure by the action of disimbibition in dry air, of hydration in water, and of low and high temperatures. When the crystalline lens of the eye of the ox is kept in a desiccator containing calcium chloride for a period exceeding 24 hours, the surface fibres become slender and assume a diffuse and marked refractivity, the chondriosomes being then no longer visible; this condition of the fibres persists even if the lens is afterwards placed in water, in which the lenticular substance swells. When the fresh lens is immersed in water, the imbibition occurring reveals itself in gradual and rapid diminution up to complete disappearance of the chondriome, that is, of the differentiated part of the lenticular protoplasm. The changes produced in the lens by the action of cold are those which are manifested after the death of the cells and are thus not directly dependent on the lowering of the temperature. The effects of a high temperature on the crystalline fibres are a gradual disappearance of the differentiated part and a precipitation of the colloids constituting the fundamental protoplasm, which loses its homogeneity and becomes granular; this is essentially the phenomenon determined by the action of acids.—**A. Galamini**: The daily thermal curve of the albino rat. In accordance with the life habits of the albino rat, its temperature-time curve exhibits two maxima, at 7 A.M. and 10 P.M.-midnight, and two minima, at 1 P.M.-5 P.M. and 4 A.M. respectively.—**C. Artom**: The circulating elements of the hæmolymph of euphyllopod crustaceans. As is the case with other entomostracans, the functions of these elements seem to consist of elaboration of the fats absorbed by the epithelium of the intestine and of transport of the elaborated fats to the various tissues.

Official Publications Received.

SATURDAY, February 25.

North of England Institute of Mining and Mechanical Engineers (Associates and Students' Section) (at Neville Hall, Newcastle-upon-Tyne), at 3.—Dr R. J. Perring: Miners' Nystagmus.—*Paper open for further discussion*:—A Contribution to the Solution of the Problem of Underground Haulage Accidents, with special reference to the Northern Mines Inspection Division, by A. M. Bryan.

Royal Institution of Great Britain, at 3.—C. Dodgson: The Life and Work of Albrecht Durer (I).

MONDAY, February 27.

Institute of Actuaries, at 5.—C. F. Warren: Further Notes on an Investigation into the Mortality Experienced by Pensioners of the Staffs of Banks and Insurance Companies.

Institution of Electrical Engineers (Informal Meeting), at 7.—L. Emanueli and others: Discussion on 130,000-volt Cables.

Institution of Electrical Engineers (North-Eastern Centre) (at Armstrong College, Newcastle-upon-Tyne), at 7.—D. S. Munro: Modern Electrical Wiring, particularly as applied to Small Houses.

Royal Society of Arts, at 8.—Dr H. Gough: Fatigue Phenomena, with special reference to Single Crystals (Cantor Lectures) (III.).

Royal Society of Medicine (Odontology Section), at 8.—Mrs Lilian Lindsay: Dentistry as one of the Fine Arts.—A. T. Marston: A Case of Necrosis of the Mandible.

TUESDAY, February 28.

Royal Society of Arts (Dominions and Colonies Meeting), at 4.30.—Sir Stephen Montagu Burrows: The Ancient Civilisation of Ceylon.

Royal Society of Medicine (Medicine Section), at 5.—Dr. H. L. Tidy: Hæmorrhagic Diathesis.

Illuminating Engineering Society (at E.L.M.A. Lighting Service Bureau), at 6.30.—W. E. Bush: The Activities of the E.L.M.A. Lighting Service Bureau.

Institution of Electrical Engineers (East Midland Sub-Centre) (at Loughborough College), at 6.45.—H. B. Poynder: Some Practical Considerations in the Design of Automatic Equipments for Heavy Traction Substations.

Institution of Electrical Engineers (South Midland Centre) (at Birmingham University), at 7.

Royal Photographic Society of Great Britain, at 7.—C. H. Oakden: The Photographic Work of the Rev. J. B. Reade.

Royal Anthropological Institute, at 8.30.—E. K. Tratman: Aveline's Hole, a late Upper Palæolithic Station in Somerset.

Institution of Petroleum Technologists (at Royal Society of Arts), at 5.30.—Prof. R. V. Wheeler and Dr. G. B. Maxwell: Flame Characteristics of Pinking and Non-Pinking Fuels.

WEDNESDAY, February 29.

Royal Institution of Great Britain, at 5.15.—Prof. J. S. Huxley: The Behaviour of Animals (II.).

Newcomen Society for the Study of the History of Engineering and Technology (at Wellcome Historical Medical Museum, 54A Wigmore Street), at 5.30.

Royal Society of Arts, at 8.—A. Crawford: Industry Fifty Years Hence.

British Astronomical Association (at Sion College, Victoria Embankment).

THURSDAY, March 1.

Royal Society, at 4.30.—Dr A. E. H. Tutton: The Hexahydrated Double Sulphates containing Thallium.—The Hexahydrated Double Selenates containing Thallium.—W. H. J. Childs: The Distribution of Intensity in the Band Spectrum of Helium: the band λ4650.—M. C. Johnson: Studies in the Behaviour of Hydrogen and Mercury at the Electrode Surfaces of Spectrum Tubes.—*Papers to be read in title only*:—Prof. W. E. Curtis: The Structure of the Band Spectrum of Helium.—Prof. H. A. Wilson: The Saha Theory and the Conductivity of Flames containing Alkali Metal Vapours.—R. G. Lunnon: Fluid Resistance to Moving Spheres.—Prof. S. Chapman: On the Brownian Displacements and Thermal Diffusion of Grains Suspended in a Non-Uniform Fluid.—N. F. Mott: The Solution of the Wave Equation for the Scattering of Particles by a Coulombian Centre of Force.—G. H. Briggs: A Redetermination of the Velocities of α-Particles from Radium C, Thorium C and C'.

Linnean Society of London, at 5.—A. M. Smith: The Algæ of a Bog. Five Years' Observations.—Dr. C. Crossland: Coral Reefs of Tahiti, Moorea, and Rarotonga.

Royal College of Physicians of London, at 5.—Dr. F. A. E. Crew: Individual, Familial, and Racial Differences in Respect of Immunities and Disease Resistance (Milroy Lectures) (I.).

Royal Institution of Great Britain, at 5.15.—Prof. F. Ll. Griffith: Nubia in Antiquity and in the Middle Ages (II.).

Institution of Electrical Engineers, at 6.—Dr. S. Z. de Ferranti: Electricity in the Service of Man (Faraday Lecture).

Royal Aeronautical Society (at Royal Society of Arts), at 6.30.—Wing Comdr. R. M. Hill: Experiences with the Baghdad Air Mail.

Institute of Metals (Birmingham Local Section) (at Engineers' Club, Birmingham), at 7.—Prof. C. A. Edwards: Gases in Metals.

Society of Chemical Industry (Chemical Engineering Group) (jointly with Bristol Section of Society) (at Bristol), at 7.30.—T. Penny: The Art of Soap Manufacture.

Chemical Society, at 8.—F. G. Mann: The Complex Salts of Divalent Platinum with αβγ-triaminopropane.

Institution of Mechanical Engineers (Glasgow Branch).—W. Watson: The Spinning of a Cotton Thread and the Machinery Used.

FRIDAY, March 2.

Royal Astronomical Society, at 4.30.—Geophysical Discussion: Periodicities. Chairman: Dr G. C. Simpson. Speakers: Sir Gilbert Walker, Prof. Turner, Mr. Yule, Mr Brunt.

Society of Chemical Industry (Manchester Section) (at Engineers' Club, Manchester), at 7.—Dr T. Callan and S. Horobin: Some Industrial Applications of the Potentiometric and Conductometric Method of Analysis.

Royal Photographic Society of Great Britain (Pictorial Group), at 7.—Annual General Meeting.

Junior Institution of Engineers (Informal Meeting), at 7.30.—A. Abbey: Some Notes on a Recent Visit to the United States of America.

Geologists' Association (at University College), at 7.30.—Prof. E. J. Garwood: River Meanders (Lecture).

Philological Society (at University College), at 8.—L. C. Wharton: Universal Language of late Dr. Mason.—Report of the Copenhagen Conference on Transcription and Transliteration.

Oxford University Junior Scientific Club (in Department of Biochemistry and Physiology, Oxford), at 8.15.—H. T. Tizard: Careers for Scientific Men.

Royal Society of Medicine (Anæsthetics and Obstetrics Sections), at 8.30.—Discussion on Anæsthesia in Obstetrics. Speakers: Dr. J. Blomfield and H. A. Richards (Anæsthetics), E. Holland and W. Gilliatt (Obstetrics), also H. E. G. Boyle and Dr. H. R. Spencer.

Royal Institution of Great Britain, at 9.—Sir Farquhar Buzzard: The Psychology of the Sick.

SATURDAY, March 3.

Royal Institution of Great Britain, at 3.—C. Dodgson: The Life and Work of Albrecht Durer (II.).

PUBLIC LECTURES.

SATURDAY, February 25.

Horniman Museum (Forest Hill), at 3.30.—Miss M. Edith Durham: Primitive Life in South East Europe.

MONDAY, February 27.

Gresham College, at 6.—G. P. Bailey: Modern Science and Daily Life: Chemistry in Industry.

Leeds University, at 8.—Dr. Ll. Wynn Jones: Recent Advances in Experimental Psychology: Applications to Education and Industry.

WEDNESDAY, February 29.

Royal Institute of Public Health, at 4.30.—Sir Robert Armstrong-Jones: The Present Legal Aspect of the Treatment of the Insane and the Mentally Defective.

Birkbeck College, at 5.30.—Dr. F. A. E. Crew: Heredity. (Succeeding Lectures on Mar. 7 and 9.)

THURSDAY, March 1.

Leeds University, at 8.—Air Vice-Marshal Sir Sefton Brancker: Some Recent Developments in Aviation.—A. N. Shimmin: Economics in Everyday Life: The Getting of Money.

FRIDAY, March 2.

King's College, at 5.30.—S. Gaselee: Greek Culture in Egypt at the Time of the Arab Invasion.

SATURDAY, March 3.

Horniman Museum (Forest Hill), at 3.30.—J. E. S. Dallas: A Naturalist at Land's End.

CONFERENCE.

February 24 and 25.

Association of Technical Institutions (Annual Meeting) (at Stationers' Hall).

Principal G. H. Austin: Commercial Education.
Principal S. Carter: Suitable Courses in Commerce for Small Institutions.
T. P. Bennett: The Technical Training of the Architect.
Principal F. E. Drury: Technical Education for the Building Trades.
F. W. Roberts: Technical Education for the Boot and Shoe Industry.

SATURDAY, MARCH 3, 1928.

The Science of Scenery.

THE study of scenery as land form has long been the subject of scientific inquiry. The slow but ever acting processes of earth sculpture have been observed, and the everlasting hills of our experience have become in mental vision but shadows of a changing earth flowing from form to form. Mountain and vale, river and coast, each can be explained from the texture of the rock and the character of the tools used by Nature in the shaping of the earth. What man naturally sees, however, is not land form but landscape, and his sympathetic appreciation of the latter rests on entirely different principles from his intellectual understanding of the former.

Landscape is too elusive in its composition, too fickle in its ever-changing form, to be bound by rigid laws of science, and yet it is obviously subject to certain laws of harmony. "Every landscape," states Prof. Alexander, "has to be composed. He who finds Nature beautiful does not manipulate with chisel or brush or voice the material he uses; he makes it beautiful by selection and composition, and, if need be, by imaginative addition. The fact is that the Nature we find beautiful is not bare Nature as she exists apart from us, but Nature as seen by the artistic eye." The laws of scenery may be compared with those of music. They are the laws of harmony.

It is to find a scientific foundation for the æsthetic study of scenery that Dr. Vaughan Cornish has of recent years turned his careful observation. Some of his results have formed the subject matter of many publications, and from these the following examples of his methods have been drawn.[1] The tones and colours of every landscape go through a cycle of change with the daily and annual revolution of the sun, and it is evident, therefore, that an æsthetic science of scenery must give an account of all these changes. They are exactly recurrent, and the results would be precise were it not that the atmosphere interposes a screen or veil of varying density according to the weather.

Dr. Vaughan Cornish is of the opinion, however, that, taking account both of the position of the sun and the state of the atmosphere, the effects observed are sufficiently definable to admit of a systematic and fairly simple description and explanation of the variation of tone and colour in the landscape. As an example he describes three varieties of atmospheric condition as they affect an extensive view of lowland. On fine days, with the exceptionally clear air which often precedes rain, there is a broad foreground of lights, shadows, and local colours. In the far distance the landscape is richly dyed with atmospheric shades of purple and of blue. The middle band of relatively unattractive tone and colour is less noticeable and perhaps is actually narrowed. This constitutes the richest daylight harmony of light and landscape on the English plain. On a misty day the farthest parts of such extensive prospects are shut out and the foreground loses in stereoscopic strength and in contrast of light and shadow. The undulations of the middle distances are then revealed in unwonted emphasis by the increased rate of atmospheric absorption and with an attractive tint of silver grey.

---

[1] Presidential Address, Geographical Association, Jan 1928. See also *Geographical Journal*, Nov. 1925; June and Nov. 1926.

During spells of fine summer weather of anticyclonic type there is no broad harmony of light and landscape in the English plain. The diffusion of the sun's rays in the upper air deprives the foreground of much of the vitality of tone and colour which are its proper charm and the means whereby it acts as a *distancer* for the rest of the landscape; the farthest undulations of the land lack atmospheric blue, and thin cloud, reflecting a crude white light from the sun, usually makes the sky near the horizon too garish to be viewed together with the distant land. These factors in tone and colour in relation to distance enter also into questions of apparent magnitude with its effect on landscape. Thus it is pointed out that distance affects the tone of clouds and mountains in opposite ways. Mountains physically compact look less massive from a distance, being then merely the opaque background of a translucent coloured medium. Cloud, on the contrary, being a sparse collection of small particles, is misty near at hand, but in its piled-up or cumulus form, appears compact and massive at a distance of a few miles. At close quarters, where clouds appear vaporous and mountains massive, the relation between them is altogether desirable.

From this example of natural scenery we turn to one in which man's work is superimposed on Nature. In his 'scenery of civilisation' Dr. Vaughan Cornish strikes a note of great practical significance. In its largest sense, Nature includes humanity, and the works of man may or may not blend with Nature to form harmonious groupings of æsthetic landscapes. The charm of old towns and places lies not solely in their age, but in the degree with which they conform to the laws of æsthetic geography. The city is the greatest expression of man's regional activity, and the stately avenues of a well-planned city are the crowning examples of one of the most characteristic contributions made by man to the scenery of the world—the vista—that pleasant path of converging lines which leads the eye to a point of rest in the far distance. The towering effect of buildings in the foreground, always considerable from the effect of vertical planes, is enhanced by columnar relief, which being imperceptible at a distance, does not interfere with the perspective of regular and strongly marked cornices reinforcing recessional effect in the remoter view.

Delight in the vista led men long since to plant trees in avenues of approach to lordly mansions, and later occurrences of a somewhat accidental character brought in the boulevard. Here we have not only the simultaneous pleasure of a vista of buildings and a vista of trees, with pleasant combination of colour in the season of the leaf, but also an enhancement of architecture, which, though appreciable at all seasons, is especially remarkable when the boughs are bare. The plane tree, which is mostly chosen for boulevard planting, is unsurpassed in winter for the combined delicacy and magnitude of the three-dimensioned lattice, which, as a foreground, makes space itself stereoscopic, distancing and magnifying the architectural background, to which, moreover, it imparts an atmospheric tone. The constructional lines of the dome, the crescent, and the archways of a stone-built bridge, are a monotonous repetition of balanced curves, but seen near by as they are in cities, perspective transforms monotony to rhythm, and the rhythm changes with every step of our approach, the curve of each element of the structure changing, the change different for each element according to its position, the change from form to form so subtle, so continuous in its flow, that it imparts the sense of infinity.

These two examples, culled from the records of Dr. Vaughan Cornish, illustrate the range of his inquiries and the principles upon which he is working. Investigation into the laws which govern scenery is of course valuable in itself. It points, however, to a practical maxim of great worth in view of man's increasing energy to change the surface of the earth. We are to-day great city builders, and even the countryside we tend to urbanise. The townward drift of men is everywhere observable, swelling to inordinate size our cities and city agglomerations. The evidence appears incontrovertible that, for good or ill, cities and culture go together. The higher men rise in he social scale, the more they appear to desire to be within the circle of civic life.

No greater example of the national danger which comes from the absence of such institutions may be found than in the report which was issued some ten years ago by the Commission of Inquiry into Industrial Unrest in South Wales (Cd. 8668, 1917). Physical conditions in the narrow valleys of the coalfield have resulted in great populations being crowded in long rows of congested villages set in the shadow of slopes falling steeply to the stream bed where roads and railway and colliery workings are placed. The beauty of Nature has been destroyed and no 'scenery of civilisation' has taken its place. Cities and civic life are absent in these valleys, and to the present dismal surroundings the report traces the prime cause of social unrest there.

It is a characteristic of the industrial age that it has been one in which humanity has been crowded together round mill and factory. We have reached a stage in the evolution of cities, however, when the vulgar ugliness of industrial towns no longer satisfies. Town planning is the order of the day, but on what principles shall we develop constructive civic art or shape the countryside? Patrick Geddes notes that Aristotle wisely insisted upon the importance not only of comparing city institutions, but also of seeing our city with our own eyes. He urged that our view be truly *synoptic*, a word which had not then become abstract, but was vividly concrete as its make-up shows. It meant the seeing of the city as a whole, like Athens from the Acropolis, or rather of Athens and Acropolis together—the real Athens—from Lycabettos and from Piræus, from hill-top and from sea. Large views in the abstract depend on large views in the concrete.

The appreciation of scenery, in this fullest sense, is, like the quality of mercy, twice blessed. To the individual it gives a new pleasure in the world around him. To a community educated in scenery appreciation, it reveals principles which should guide constructive art in Nature, principles which will influence for abiding good the resettlement of England and of other countries consequent on a vigorous development of the economic resources of the earth with new means of transport and communication. The diagnosis of scenic beauty made by Dr. Cornish in his addresses should appeal particularly to all who are concerned in regional surveys and the preservation of rural scenery or the relation of architecture to landscape.

Palæometrology.

(1) *Glass Stamps and Weights: Illustrated from the Egyptian Collection in University College, London.* By Sir Flinders Petrie. Pp. vi + 28 + 26 plates. (London: British School of Archæology in Egypt, 1926.) n.p.

(2) *Ancient Weights and Measures: Illustrated by the Egyptian Collection in University College, London.* By Sir Flinders Petrie. Pp. vi + 51 + 54 plates. (London: Department of Egyptology, University College, 1926.) n.p.

FIFTY years ago there was published in London a small book with an ambitious title, "Inductive Metrology." It was an account of the author's attempts to discover from ancient structures, by an analysis of their ascertainable dimensions, the basic units of linear measurement that must have been employed by their builders. The adjective served to direct attention to the contrast between the author's method and the prevalent practice of spinning unverifiable hypotheses out of the vague data furnished by remains of a purely literary character. The method was not new, even in relation to the investigation of ancient metrology—it had been used by Newton in his endeavour to ascertain the length of the sacred cubit from certain dimensions of the Great Pyramid—but it had never hitherto been exercised upon so large a scale.

Now the applicability of the inductive method depends greatly upon the extent to which trustworthy observational data are envisaged, and this again depends upon the degree to which relevant material is available for observation. These considerations were clearly appreciated by the author of "Inductive Metrology," and, seeing that the supply of material or of observational data were deplorably lacking, such trivialities having been almost completely ignored alike by writer and excavator, he set himself with a will to remedy the deficiency. As a consequence the name of Flinders Petrie has become inseparable from mention not only of ancient metrology but also of scientific Egyptology in general.

Within a few years of the publication of his initial essay he was excavating, on behalf of the newly formed Egyptian Exploration Fund, the ancient cities of the Delta, whence, especially from Naucratis, Tanis, and Defenneh, he recovered *inter alia* great quantities of weights of various ages, shapes, sizes, materials, and states of preservation. To the data obtained from this material, carefully corrected for estimated losses and accretions, he applied the method of statistical analysis which had proved so effective in his study of linear measurements, and arrived at certain conclusions with regard to ancient units of weight, duly publishing his results in the reports of his excavations. Since that time the store of Egyptian weights recovered has been periodically augmented through the labours of the British School, and now amounts to about six thousand specimens, of which number two-thirds are preserved in the collection at University College, London, together with a smaller but still important assemblage of measures of capacity and of length, and a few examples, mostly of late periods, of balances and steelyards.

The present volumes are primarily of the nature of a catalogue of all objects of a metrological character contained in that collection, and as such they have a value proportional to the importance and uniqueness of the collection; but they are considerably more than mere descriptive enumerations: they are studies in the art of scientific classification. In the introduction to the larger work, Sir Flinders Petrie modestly disclaims any attempt to deal with the whole field of ancient metrology. "This," he says, "is only a publication of material, and in the necessary classification of it we may reach some solid foundation for the whole subject." Whether the foundation that has been reached is solid enough to support a permanent edifice time will no doubt show, but if the prodigious industry, meticulous care, unwearying patience, and searching breadth of view to which these two books bear witness are insufficient for the purpose, we may have long to wait for the provision of a sounder basis.

All who have at any time been led by circumstance to seek for authentic information regarding ancient units of weights and measure, and have found themselves floundering amongst competing theories of derivation and inter-relationship, or staggering through mazes of pseudo-scientific hierophantics, must surely turn with grateful relief to the findings of one who restricts himself to the consideration of actual facts. We have here no airy speculations, no arguing from questionable premises or gratuitous assumptions, but the results of a prolonged and patient examination, at every practicable angle, of a vast amount of material evidence.

Naturally these results can scarcely be expressed in the form of pocket-book tables, nor do they readily lend themselves to popular presentation, though it must be admitted that they are set forth with as much clearness as the complexity of the subject will permit. In order to form some idea of that complexity, it should be realised that as regard the weights alone the objects dealt with are from periods ranging from an early prehistoric (Amratian age to the thirteenth century A.D.; that severa systems, often with overlapping multiples and submultiples, were in simultaneous use; that individual weights might vary considerably from the standards they were intended to represent; that the mean values of the basic units fluctuated throughout the ages; that some systems were confused by the existence of single and double (or 'light' and 'heavy') varieties of the same unit that in any given system binary, ternary, decimal and other series of multiples might exist side by side; that most of the specimens bear no markings and that where markings are found they are frequently of an ambiguous or misleading character that in many instances elaborate tests and calculations have been necessary in order to allow for injury or corrosion, or both, in estimating the original weight.

With these considerations in mind, one may without difficulty credit the statement made in the larger volume that "a large amount of tentative tabulating had to be done, on various lines, before a conclusive method of handling each part of the material could be reached."

It would, of course, have been impracticable to burden the catalogue with details of all this experimental work; all the 'scaffolding,' to use the author's own expression, has been removed and the extent of it might not be realised from a mere perusal of the stated conclusions.

With regard to the weights, excluding the Arabic series, it would appear that eight fundamental units emerge from the investigation, each forming the basis of a system. The specimens are catalogued in 'registers' and grouped under their respective systems, the serial number, material, form, ascertained weight, numercial relationship to basic unit, the value of that unit and details of markings, etc., in respect of each specimen being compactly tabulated. The ancient names of the basic units were not in every instance easy to determine; indeed, but for the clues furnished by the results of recent progress as regards Palestinian weights, it is doubtful whether it would have been possible to discover the names of certain of the units or to disentangle completely the corresponding systems.

In this connexion it is to be noted that the weights are very rarely marked, like modern weights, with their value in terms of a stated denomination. When they are marked at all it is often with some numeral which may refer to their equivalence in some system other than that to which they belong; it is as if a kilogram weight were to be marked '35' because it is roughly equivalent to 35 ounces. Even where a denomination is marked, it is apt to be nothing more than the designation of some sort of a multiple common to more than one system, the term *teben* or *deben*, for example, being used for a weight of 10 qedets or one of 10 peyems (cf. *mina*, *shekel*, etc.). Fortunately, however, the names of three standards of weight, *Necef*, *Peyem*, and *Beqa*, have been found marked on weights from Palestine belonging respectively to hitherto unnamed series which occur also in Egypt, and others were discovered which bore, in common with one Egyptian example, a sign construed as a monogram of the letters X and O, and hence, having regard to the fact that some syenite weights of apparently the same series are shaped like the shell of the cowry, to be an abbreviation for the Greek name for that mollusc, χοιρίνη. The ancient names of the four remaining basic units having been already established on abundant evidence, these Palestinian sidelights afforded a very convenient key to the solution of the nomenclature problem and to the elucidation of all the Egyptian weights hitherto unclassified.

Lest the argument outlined above for the adoption of the name *khoirine* be criticised as far-fetched, it is only fair to add that it appears to receive no small support from the information contributed by competent zoological authorities, whose observations are appended to the text; it is hard to resist the conclusion that the standard derived its name and form from the Mediterranean *Cypræa lurida*.

The eight standards recognised, then, are: (1) the *peyem*, varying from about 112 to 125 grains; (2) the *daric*, a very early Mesopotamian unit, from 124 to 133 gr.; (3) the *stater*, so called after the famous gold coinage of Philip of Macedon though of much earlier origin, 132 to 138 gr.; (4) the typically Egyptian *qedet*, 137 to 152 gr.; (5) the Syrian *necef*, 152 to 169 gr.; (6) the *khoirine*, 170 to 189 gr.; (7) the *beqa*, also known as the 'gold' standard on account of the frequent occurrence of the 'nub' sign on its examples, 187 to 214 gr.; and (8) the *sela*, or Phœnician standard, 209 to 227 gr. By reason of the variation exhibited in their different examples, these units form a continuous overlapping series, but there are no grounds for concluding that they have diverged from a common predecessor. In an interesting appendix it is shown that, with the exception of the peyem and stater, the same standards must have been used in the weighing of the precious metals at a very early time in western Europe. A remarkable comparison is drawn between the widely spread system which connected Egypt with Babylonia, Assyria, etc., and those of India, China, and Etruria, leading to some curious speculations regarding the Etruscan migration.

Although, as already stated, the work is primarily a catalogue of the Gower Street collection, the very useful step has been taken of appending in brief outline an account of various other collections of weights to which reference is made in the main text, including a hitherto unpublished list of the weights in the Græco-Roman Department of the British Museum compiled by the author forty years ago and used by him in preparing his well-known article in the "Encyclopædia Britannica." No reference, however, is made to the Egyptian weights mentioned by Chisholm in his report on various ancient weights in the British Museum in 1873 (Annual Report of Warden of the Standards, 1874–5, Appendix XI.), though the data there given would appear to be not altogether devoid of interest.

In a chapter devoted to the steelyards, a very detailed account is given of the two large and elaborate specimens of Arabic date, the remaining sixteen examples being of Roman times, and a highly ingenious method is explained for arriving at the weight unit on which the graduations are based, notwithstanding mutilations and the absence of counterpoises. The balances, including the wonderfully preserved set in a combination 'pocket' case reminiscent of those in use in Great Britain a few centuries ago, are considered not with the steelyards but separately, after the measures. Only one example is pre-Roman, and that is apparently prehistoric, a red limestone scalebeam about 3½ in. long. The inclusion of a George III. coin balance, a Chinese balance, an eighteenth-century nest of avoirdupois weights, and similar oddments in this section, strikes a note of incongruity.

The basic units deduced from the study of the measures of capacity are: (1) the Syrian standard, of 20·8 or 21·4±0·3 cub. in.; (2) the native Egyptian *hen*, 29·0±0·3 cub. in.; (3) the Syrian *log*, 33·1±0·2 cub. in.; (4) the Attic *kotyle*, 17·2±0·2 cub. in.; and (5) the Persian *kapetis*, 74·9±0·3 cub. in. Most of the vessels in this section, like many of the weights, have nothing to show that they are intended as measures (or weights) except the fact that they are found to stand in more or less definite relationships to one another as regards capacity. One, however, is graduated internally and another is marked as "1/8th"; these prove to be respectively a 2-*hen* subdivided into ½-*hen* and a 1/8th *ken*. The weight of water-content of the measures shows some slight agreement with the systems of weight units so far as the *ken* and the Syrian standard are concerned, but practically none otherwise. The theory of a primitive connexion between units of weight and of lineal measure receives no support whatever; indeed, such a connexion is shown to be *prima facie* improbable.

The lineal measures in the collection include eight wooden cubits, some as old as the 12th dynasty, showing the royal cubit of about 20·6 inches divided into seven palms; four rods showing the Assyrian and Jewish cubit of 21·4 inches divided into six palms; and a limestone standard measure showing a 7-palm cubit of 26·8 inches, besides various fragmentary specimens. The description of this material is followed by a discussion of the relationship between the last-named standard and those of northern countries, some striking parallels being set forth.

The smaller volume is concerned solely with the glass stamps and weights characteristic of the Arabic period. Its range of interest is accordingly more circumscribed, though even here the non-specialist may find food for reflection in the evidence afforded of the astounding degree of precision to which the medieval craftsmen were able to adjust their weights. We know from other sources that the Arab scientists bestowed great attention on the development of the balance, both for weighings in air and for the Archimedean determination of specific gravities; but even so, it is rather startling to learn that they were in fact able, during their best period (during the caliphate of El Mahdy, *circ.* A.D. 775–785), to turn out weights agreeing with the standard and with one another to within a few thousandths of a grain, or about 0·01 per cent. of their nominal weight!

To the collector this catalogue should be of the highest value, for not only is the series dealt with larger than either of those previously listed (Brit. Mus. Coll., *catal.*, Lane-Poole, 1891, and the Fouquet Coll. at Cairo, *catal.*, Casanova, 1893), but also greater attention has been bestowed on exactitude of the weights and fuller use has been made of photographic illustration, every specimen except duplicates from the same die being portrayed. As the inscriptions are not always sufficiently clear in the photographs, they are all reproduced opposite the plates. The average error and the variation of the average standard of the *dinar* and the *dirhem* over the whole period are shown graphically. Of these two standards, the former varies from about 62 to 66 gr., the latter from 44 to 48 gr. The principal multiples appear to be the *wuqiyeh* o 10 dirhems (av. 443·4 gr. in glass weights and 445·6 in metal) and the *rotl* of 12 *wuqiyehs* (av 5814 gr.), but many of the earlier weights are marked as a *fels* of so many *kharrubehs*. The *kharrubeh* or *carob* (also = *qirat*; Gr. *keration*) is about 3 grains. Our own *carat*, legalised in 1913 as the 'Metric Carat,' is 0·2 gramme = 3·086 gr. In addition to the registers of weights there is given a chronological scheme of caliphs, governors, and other officials, also a transliteration of the curious monograms on the Byzantine *solidus* weights.

In conclusion, it certainly seems no extravagance to state of these two volumes that not only do they constitute a worthy record of a unique collection, but that they may also be regarded, especially the major work, as forming a most valuable contribution to the foundation of a rational system of palæometrology.

W. H. Matthews.

The Study of Living Machinery.

(1) ***Muscular Movement in Man: the Factors governing Speed and Recovery from Fatigue.*** By Prof. A. V. Hill. (The George Fisher Baker Non-resident Lectureship in Chemistry at Cornell University, Vol. 3.) Pp. vi + 104 + 5 plates. (3) ***Basal Metabolism in Health and Disease.*** By Prof. Eugene F. Du Bois. Second edition, thoroughly revised. Pp. viii + 17-431. (London: Baillière, Tindall and Cox, 1927.) 22*s.* 6*d.* net.

(1) It is not many years since critics of academic physiological research work were accustomed to illustrate their arguments by referring to the uselessness of the investigations which were being made on muscle function. It has now become clear that these investigations laid down basic knowledge which to-day underlies the scientific study of muscular activity in athletics, medical science, and industrial problems. In the preface of his book, "Muscular Movement in Man," Prof. A. V. Hill recounts an experience in America when, on being challenged by a member of the audience at the conclusion of a lecture to prove the value of his work, he replied that he performed experiments

because they were amusing. While it is apparent that Prof. Hill finds great amusement in his investigations, yet few physiologists are able to demonstrate the application of their work to the elucidation of practical problems as Prof. Hill has done in his recent publications.

The present-day views of muscular contraction have their origin in the investigations of Fletcher and Hopkins (1907) on the lactic acid content of muscle. These observers studied the lactic acid content of muscle under a variety of conditions, and showed that when a fatigued muscle was placed in oxygen the muscle regained its excitability and the lactic acid fell in value. These experiments suggested that lactic acid was formed by the breakdown of a carbohydrate substance (glucose) on contraction of muscle, and that the lactic acid played an important rôle in the initiation of the contraction. These investigations have, in recent years, been extended and confirmed. In the contraction of muscle, lactic acid is the most important known intermediary. It is probable, however, that the lactic acid is not further oxidised, but is re-transformed through hexosephosphate and glucose to glycogen, the energy for the process being supplied by the oxidation of a further supply of sugar; carbon dioxide, which is increased by the contraction, being formed from this later product.

The investigation of heat changes during muscular activity have confirmed the chemical findings. Recently attention has been directed by Prof. Hill and his co-workers to the viscosity of the muscle, and they have shown that during contraction the viscosity of the frog's muscle appears to rise about twenty times. The effects of viscosity changes are clearly seen in investigating the speed of shortening and the energy of contraction, for, on contraction of the muscle, the viscous elements act as a resistance to the movement. Therefore the greater the speed of shortening, the larger the proportion of energy wasted; on the other hand, if the muscle shortens too slowly, the energy is not utilised for work but is converted into heat. At some intermediate point an optimum speed may be obtained where the maximum work is done in a given time.

In "Muscular Movement in Man," which is based on a series of lectures delivered at Cornell University in 1926–27 under the non-resident lectureship in chemistry, Prof. Hill has applied the knowledge gained by investigations on the isolated frog's muscle to the problems of muscular movement in man with particular reference to athletics. The author shows how, from measurements of the oxygen consumption, information may be obtained of the change taking place in the muscle during exertion. The resting oxygen consumption is accurately measured and compared with the oxygen used during the period of exercise and period of rest following the exercise. During the period of exertion the oxygen which can be inspired is not sufficiently large to prevent the accumulation of lactic acid, and excess of oxygen must therefore be taken in during the recovery period to restore the muscles to their previous condition. The amount of oxygen used, in excess of the resting level, during the period commencing at the moment exercise ends and ending when recovery is complete, is called the 'oxygen debt.' The greatest speed which can be maintained during exercise is therefore determined by considerations of the energy expenditure. An example is given on p. 23, where the author estimates that a fit man might climb the Woolworth Building (792 ft.) in New York in eight seconds, finishing with an oxygen debt of fifteen litres, which is about all a man can tolerate. A footnote adds that the newspapers reported that the feat had actually been accomplished in nine seconds.

By an ingenious electric timing method the speed of a runner has been measured for varying distances. Plane coils of wire connected with a galvanometer were arranged parallel to the track. The runner carrying a magnet induced a current in the coil as he approached, which was recorded by the galvanometer. The author's experiments show that the slowing up during a maximal effort depends not only on the extent of the oxygen debt, but also on the increased viscosity of the fatigued muscle. The best athlete investigated took a longer time than other runners to attain his maximal speed in a 200 yards sprint, but this is due to the fact that his speed was considerably greater. It is suggested that his success in attaining so high a speed, while partly due to his skill in running, is mainly dependent on the low viscosity of his muscles. The important rôle played by the muscles in aiding the circulation during exercise is emphasised in the tables where a comparison of the oxygen consumption per kilogramme per minute is made between oarsmen and runners. The runner, by virtue of the pumping action of the muscles increasing the circulation rate, can consume per kilogramme of body weight considerably more oxygen than an oarsman.

"Muscular Movement in Man" is a book of exceptional interest. It gives the reader a clear and interesting account of muscular activity in relation to exercise, and Prof. Hill may feel assured that his lectures will stimulate others to investigate the problems.

(2) In "Living Machinery," Prof. A. V. Hill has written in simple language a description not only of the muscles and functions of the body and how they work, but also of the body functions as a whole. The book is undoubtedly one of the best popular scientific expositions of physiology which has been published. It will be read with benefit by all those who are interested in their own machinery or the progress of physiology. Boys and girls of a mechanical and scientific turn of mind will be stimulated by the description of experiments carried out by Prof. Hill and his staff of four, whose ages ranged from six to eleven years. The book will also serve to demonstrate how the principles of chemistry and physics enter into our own daily life and regulate the activities of the tissues of the body.

(3) The metabolism of the body at rest has been recently dealt with by E. E. Du Bois, Medical Director of the Russell Sage Institute of Pathology. The work of Du Bois on the measurement of body surface in man and on the metabolism in diabetes and fever is of fundamental importance, while his figures for calories per square metre per hour in normal individuals of different age and sex are generally used as the standard from which the percentage increases or decreases in metabolism occurring in disease are calculated. The book, less condensed than the monographs of King and McCann, and containing less detailed description of technique than that of Boothby and Sandiford, is admirably written and covers the ground in a manner which leaves little to be desired. The book, though written for those "engaged in the practice of medicine and surgery, for medical students, for physiologists, and for dietetians," should also be of value to general biologists interested in the problems of respiration and metabolism.

The schools of nutrition in America, founded by Benedict and Lusk, of whom Prof. Du Bois is a distinguished pupil, have for some years been applying the results obtained on studies of normal human basal metabolism to the problems of clinical medicine. The success of these methods may be judged by the wealth of information which has been accumulated on disorders of nutrition, disease of the thyroid gland, blood, and fevers. This book affords an excellent example of the extent to which quantitative methods of measurement may be applied to the study of the normal and disordered functions of man.

Modern Physics.

Lehrbuch der Physik. Von Theodor Wulf, S.J Pp. xiv + 512. (Freiburg im Breisgau: Herde und Co., G.m.b.H., 1926.) 17·50 gold marks.

WULF'S "Lehrbuch" is the most recen edition of P. Ludwig Dressel's "Elementares Lehrbuch der Physik," which first appeare more than thirty years ago. It is not a rehash o the original or later editions, but an entirely new book. That this should be so is self-evident in view of the fundamental advances and far-reaching discoveries of the last few decades. During last century the main object of the science consisted i the observation and description of natural phenomena, and in the formulation of 'laws' embodyin the results obtained. Now we seek to 'explain them in terms of the smallest constituent brick of the material world. From gross matter we hav passed by way of the atom and molecule to th electron and the proton.

During recent years there have been many books, both for the layman and for the specialist, dealing with the newer physics. Here we have a book which deals with the fundamental results of the whole of physics, and is written from the modern point of view. Of mathematics, the book contains just that amount necessary, in the author's opinion, to stimulate a fuller appreciation and understanding of the subject. But it is not a text-book in the usual sense, that is, for students studying for examinations, though all who read it must derive much benefit and a keener and more enlightened grasp of the subject. It is not intended for the 'man in the street,' but for the young physicist, the engineer, the chemist, the schoolmaster, and in fact for anyone who would welcome an authoritative and trustworthy account of the present-day structure of physics, without all its finer detail.

The distribution of the subject matter is somewhat off the usual lines, and possesses many advantages over the pigeon-holed system of most text-books of physics, ancient and modern. Thus, instead of subdividing the subject into mechanics, heat, light, sound, magnetism, and electricity, the author has presented his subject under four main heads.

In Part I., "Die Körperwelt," perhaps best rendered as "The Material World," the author deals with bodies as they are directly revealed to our visual sense, and includes sections on the fundamental ideas of motion, the motion of bodies, the force of gravitation and general attraction of masses, elasticity, impact, general wave theory, and sound. Now we have ample evidence that matter is composed of small particles—atoms—and although we cannot see them, we recognise their existence and know some of their properties. This aspect of physics is dealt with in Part II. on the atomic structure of the material world, which contains sections on the system of the elements, the three states of aggregation of matter, temperature, specific heat, heat and change of state, the three principles of thermodynamics, and the atom. Not content with the knowledge of the atomic constitution of matter, the physicist has probed in turn into the structure of the atom and its consequences, with which Part III. is concerned. In this, the sections deal respectively with magnetism, electrostatics, electric currents, 'interactions' between electricity and magnetism, electrolysis, ions and electrons, radioactivity, electro-magnetic rays, and atomic constitution. Finally, there are numerous phenomena which, apart from ponderable matter, require a medium—the so-called ether—for their explanation. Part IV. is devoted to such etherial phenomena, and contains sections on 'disturbed' (reflection, refraction, etc.) and 'undisturbed' propagation of light, interference and diffraction, polarisation, light and colour, and the ether—treated also from the relativistic viewpoint.

After a careful perusal of this book, one feels that the author has departed from the traditional 'dry as dust' presentation of physics which is the bugbear of so many young students. For this it is to be feared our examination system is largely to blame, for it has tended to foster the grouping of the branches of physics into somewhat disinterested watertight compartments. A treatment of physics on the lines of Prof. Wulf's "Lehrbuch" would, we believe, be of inestimable value to the junior classes in our universities, and serve to give them some of the enthusiasm for their subject that one usually meets with only amongst more advanced students.

Our Bookshelf.

A Dictionary of Applied Chemistry. By Sir Edward Thorpe, assisted by eminent Contributors. Revised and enlarged edition. Vol. 7: Thalenite to Z. With an Index to the whole work by Frances M. G. Micklethwait. Pp. viii + 765. (London: Longmans, Green and Co., Ltd., 1927.) 60*s.* net.

THE first duty of a reviewer of the seventh and final volume of "Thorpe's Dictionary" is to congratulate those who have been responsible for the enterprise on the successful completion of their arduous task. As the first volume appeared in 1921, the publication of a fresh volume has become almost an annual event; but only five volumes had been completed when Sir Edward Thorpe died in February 1925. The work on the two remaining volumes has therefore been completed by Dr. Forster Morley, whilst Dr. Micklethwait has prepared an index to the whole work, which occupies more than 150 pages of the text of the last volume.

As in the earlier volumes, the emendation and enlargement has been so well distributed that it is not easy to discover where the new material has been incorporated, but the present volume is noteworthy for the addition of two articles on toluene and xylene by Prof. Rowe and Dr. Davies, which account for nearly 120 extra pages, and for an article by Prof. Briscoe on the physical and chemical properties of water, which covers rather more than 40 pages, compensation being provided by an expansion of about 4 pages in the article on wine. Prof. Hopkins has also contributed a new article on vitamins. These additions provide evidence of the thoroughness of the revision, and justify the expectation of a long lease of life for a work of reference which first appeared in 1890–1893.

Katalyse mit kolloiden Metallen. Von Walter Hückel. (Kolloidforschung in Einzeldarstellungen, herausgegeben von Richard Zsigmondy, Band 6.) Pp. viii + 86. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1927.) 6 gold marks.

IN presenting this account of laboratory methods of using colloidal metals as catalysts, attention is directed mainly to the work of Paal and of Skita on the application of metals of the platinum group to the hydrogenation of different types of organic compounds. The earlier investigations of the phenomena accompanying the decomposition of hydrogen peroxide are only introduced to elucidate the theory of the kinetics of colloidal catalysis, since they form the subject matter of a separate volume in the same series. The use of colloidal metals has greatly simplified the important process of hydrogenation, since many reductions can be carried out in solution at ordinary temperatures.

Paal's method has given very valuable results, particularly in the terpene series, but it is much more limited in scope than that of Skita, which appears to be applicable to most unsaturated compounds. Since, however, the latter method requires special apparatus in which a pressure of 2-3 atmospheres can be developed, it has received much less attention. Much less is known about the application of colloidal catalysts to the reduction of inorganic compounds or to oxidation processes. The volume ends with a chapter on the mechanism of catalytic hydrogenation, in which theories of hydrogen activation are discussed.

Evolution of the Drama in Hull and District. By Thomas Sheppard. Pp. xii + 254. (Hull: A. Brown and Sons, Ltd., 1927.) n.p.

IN this volume the versatile curator of the Hull Museum has published, with some expansion and numerous illustrations, an address delivered by him in his office of president of the Hull Playgoers' Society. Properly speaking, theatrical history in Hull does not begin until 1767, except for an ordinance of the Mayor and Corporation forbidding burgesses to attend performances of the players in 1599. Nor does Hull itself contribute much to the history of the drama, although Beverley, which comes within Mr. Sheppard's area, celebrated Corpus Christi with the usual plays and gild processions, and is also credited with the first mention of miracle plays. Mr. Sheppard has drawn liberally on the material available from York, Chester, and elsewhere in elucidating the early stages of his subject. No Corpus Christi plays are recorded in Hull; but it is interesting to note that there was a performance of the Noah play on Plough Monday in medieval and later times, when a large ship which hung suspended in the transept of Holy Trinity Church was taken down, dragged round the town, and then served as the ark of the play in front of the church. Mr. Sheppard describes a Ploughboys' Monday celebration which he himself saw in his early youth, when a group of rustic players went from house to house and acted a play which seems to have been of the usual folk drama type, culminating in the killing of one of the characters.

The Mathematics of Engineering. By Prof. Ralph E. Root. Pp. xiii + 540. (London: Baillière, Tindall and Cox, 1927.) 34*s*. net.

AMERICAN text-books of mathematics rarely find favour in Great Britain, and this work, written by a professor of the U.S. Naval Academy to meet the requirements of student officers, is scarcely likely to prove an exception. The tendency throughout is to give an empirical and mechanical knowledge of the subject, so that the engineer uses his mathematics merely as a tool. This is typified by the fact that a student is encouraged at an early stage in his mathematical career to rely on a table of integrals, rather than to acquire the facility for evaluating them independently. The degree to which the subject has been condensed may be judged from the fact that the theory of errors, method of least squares, and curve fitting have been dismissed in 42 pages.

The printing is marred by the rendering of all letters used as symbols in ordinary Roman characters instead of in the customary italics. In these days of monotype setting such an innovation cannot be defended on the grounds of economy, and, as it increases the difficulty of reading, it is to be hoped that other publishers will not follow suit.

L. J. C.

Spherical Harmonics: an Elementary Treatise on Harmonic Functions, with Applications. By Prof. T. M. MacRobert. Pp. xii + 302. (London: Methuen and Co., Ltd., 1927.) 15*s*. net.

THE object of this work is to provide a text-book on the elements of the theory of spherical harmonics with applications to mathematical physics so far as this can be done without employing contour integration. Within these limitations the author has certainly provided a useful book. The actual treatment of spherical harmonics occupies ten chapters with gravitational, electric, and magnetic applications. There is also a treatment of spheroids. No applications to hydrodynamics are mentioned. Chap. i. contains an account of Fourier expansions subject to Dirichlet's conditions, which should prove useful. Chap. ii. deals with the conduction of heat, and in Chap. iii. an interesting discussion of the vibrations of harp, violin, and piano strings is given, which offers a striking contrast in the effect of initial conditions. The last three chapters of the book give a valuable account of Bessel functions and their applications to the vibrations of a circular membrane and the flow of heat.

L. M. M.-T.

Mathematical Statistics. By Prof. Henry Lewis Rietz. (The Carus Mathematical Monographs, No. 3.) Published for the Mathematical Association of America. Pp. xi + 181. (Chicago and London: The Open Court Publishing Co., 1927.) 10*s*. net.

PROF. RIETZ aims at explaining the mathematical theory underlying modern statistical analysis, and in particular to correct misleading impressions as to the place and importance of probability theory. He has succeeded in giving an admirable and connected survey of the more important methods, including an account of the Lexis theory. The mathematics used are elementary and the style elegant, but the language is that of the mathematician, and it is doubtful whether the author will succeed in reaching those whose knowledge is confined to the elements of the infinitesimal calculus. From the point of view of readers of this class, the book would have been improved by a list of definitions of the terms employed. To those of mathematical tastes the book can be recommended as offering a convenient conspectus of an important field of thought. L. M. M.-T.

Studies in Psychology: Memory, Emotion, Consciousness, Sleep, Dreams, and allied Mental Phenomena. By Dr. William Elder. Pp. xv + 212. (London: William Heinemann (Medical Books), Ltd., 1927.) 8*s*. 6*d*. net.

DR. ELDER writes very sincerely as a neurologist who is much interested in psychological theory but is quite unable to think of a mind without a brain. He has no sympathy with modern psycho-analytic theory and writes as a whole-hearted behaviourist. He looks on sleep as an instinct which has become a habit. Dreams are to him easily explained on old-fashioned lines without any need to invoke the aid of the censor, the symbol, manifest or latent contents, or any other Freudian concept. The author very sensibly points out that the interpretation of dreams must by their very nature be largely a matter of guess-work and far removed from any claim to scientific accuracy. Altogether a most refreshing book in an age where one has almost forgotten the existence of any other dream theories than those of Freud, Jung, Adler, and Rivers.

The Nebulium Spectrum.

In an interesting note by C. T. Elvey (Nature, **121**, p. 12, Jan. 7, 1928) a calculation has been given of the "density necessary to produce the nebulium spectrum," the example considered being the nebulosity originating in the new star Nova Aquilæ, 1918. The outburst of this star was observed early in June 1918; by October a bright nebulous envelope had appeared around the star; it continued to spread as long as the star was under spectroscopic observation (August 1926). The outward flying gases had an average velocity of some 2000 km./sec. The N_1 and N_2 lines (5007 A. and 4959 A.) were recognised in the spectrum about 19 days after the outburst. At that time the density of the envelope would be of about 10^{-17} grams/c.c. In the first years of the existence of the envelope the light of the gas consisted mainly of the nebulium lines N_1 and N_2; in 1926, however, these were extremely faint, and most of the light came from the Balmer lines of hydrogen and 4686 A. He^+ (E. Hubble and J. C. Duncan, *Astrophys. J.*, **66**, p. 60; 1927; and Plate IV.). Nine other novæ give similar density, 10^{-19} to 10^{-20} grams/c.c., that is, about 50 molecules/c.c.

This constancy was taken as indicating that "there is a limiting density above which the conditions are unfavourable for the production of the nebular spectrum" (10^{-17} grams/c.c.). This corresponds to some millions of H atoms/c.c., the free path being of the order of hundreds of kilometres. Forbidden lines, however, have been actually obtained at higher pressures, and without denying that the density is of great importance, it seems to us that another factor has been unduly neglected: the temperature. It is evident that the expansion of the star was accompanied by changes in temperature or at least by changes in the composition of the spreading matter. It is generally recognised at present that the light observed in nebulæ is in some way caused by neighbouring stars (in the diffuse galactic nebulæ) or where the luminosity is arranged around a brighter nucleus (planetary nebulæ) by the light from the central star. The nebulous material must be in a physical state sensitive to stellar radiation and close enough for the density of radiation to be effective.

An attempt has been made (Zanstra, *Astrophys. J.*, **65**, p. 50; 1927) to show that the light emitted by the diffuse nebulæ is, in the case of the Balmer lines, at least, due to the recombination of positive ions and electrons. The total number p_n of electrons which is captured by the nth level of the H atom is, according to Kramers, about

$$p_n = \frac{\dfrac{1}{n + Cn^3}}{\displaystyle\sum_{n=1}^{\infty} \frac{1}{n + Cn^3}} \text{ where } C = \frac{\frac{1}{2}mv^2}{W_1}$$

(W_1 the ionising energy of the first excited level, m and v the mass and the velocity respectively of the electron). If $\frac{1}{2}mv^2$ of the electron is comparable with W_1, an appreciable fraction of electrons will be captured by the first levels. Although the Balmer series and the associated continuum have been observed in many nebulæ, it is by no means clear how recombination phenomena can account for the majority of these clouds. The density of the gas itself is usually smaller than the concentration of charges obtainable in the positive column of a (rare) gas discharge, and in this case recombination is negligible.

Any theory of nebulæ emission has to account for the wide differences in the spectra of nebulæ. In this respect Hubble's results as to the type of stars associated with the gaseous matter are important (*Astrophys. J.*, **56**, pp. 162 and 400; 1922). The light emitted by the nebulæ is very often different from the spectra of these centres. There is, however, a close correspondence in that nebulæ giving bright lines are always connected with stars of earlier than B1 type, whereas when later types are involved the nebular spectrum is continuous, with or without dark absorption lines. B1 type stars correspond to a temperature of about 20,000°.

The typical nebular lines N_1 and N_2, the forbidden lines between the low-lying metastable levels of O^{++}, are as a rule much stronger in the planetaries than in the diffuse nebulæ. In the diffuse case H_β is about as strong as N_1, in the planetaries the ratio is $N_1 : N_2 : H_\beta = 10 : 3 : 1$. The strengthening of the nebulium lines in the planetaries is not accompanied by a corresponding increase of the continuous spectrum of the nuclei in this region; but the maximum of the continuous nuclear spectrum is shifted to the violet as compared with that of the stars associated with diffuse nebulæ. Thus the planetary nuclei have an extraordinary intensity in the ultraviolet, the maximum being certainly at a wavelength less than 3300 A. There are now two points to which we should like to direct attention. The first is that the energy to excite the nebulium lines would be very small if the material (oxygen) were already in an ionised state, so that the connexion between strong ultra-violet spectra and nebulium lines is difficult to understand on that basis. The second point is that the lines are essentially emission lines and have as yet no importance in absorption spectra. Both facts lead to the conclusion that the oxygen which is responsible for the nebular lines cannot be in an ionised state, but must be present as a molecule or molecular ion. As a molecular ion it ought to show absorption bands situated in the visible spectrum.

That forbidden lines between low metastable states of an atom may be expected from dissociating molecules was first pointed out by the authors in a paper published more than half a year ago (*Proc. Roy. Can. Soc.*, vol. 21, p. 27; 1927: cf. the discussion of the low metastable levels of I_2). We should like to add that not only the emission of forbidden lines must occur, but also their absorption. In the case of mercury vapour, for example, the heat of dissociation of the molecules is low; under the conditions of the experiment it is of the order of the energy of the faster molecules, so that a large number of molecules break up into atoms, while other atoms recombine to maintain the equilibrium. So long as in this process one mercury atom remains under the influence of the field of its companion of late, it may absorb forbidden lines. That forbidden lines are absorbed has indeed been strikingly demonstrated by Lord Rayleigh (*Proc. Roy. Soc.*, vol. 117, p. 294; 1927).

These relations will be more closely analysed in connexion with other work; their importance for our knowledge of the constitution of stars is evident.

The Hydrogen Molecule.

In his very interesting letter on this subject to Nature of Jan. 28, Prof. Birge has decided that the first of the two alternatives which I proposed for the structure of the spectrum of H_2 is correct. I should have been very much pleased to obtain the support of so eminent and experienced a band spectroscopist for either view; but at the present time there is no material divergence between us. The last of the two or perhaps three papers [1] which Prof. Birge traverses was written nearly a year ago. At that time it was obvious that there was a misfit somewhere, and I indicated two alternative positions for it. Since then much information about the extreme ultra-violet, as well as the visible spectrum, has come to light. There are also the results of the calculated structure of the hydrogen molecule which have been obtained by the new quantum mechanics. It now seems fairly certain that the suspected coincidence of my 2^3P level with Dieke and Hopfield's C level is an accident. The case for the coincidence of my 2^1S level with their B level is much more convincing.

If this coincidence is correct the following fact is very curious. On Werner's plates taken in the visible, which he has kindly allowed me to inspect, I find the violet bands $2^1S - 3^1P$ and $2^1S - 4^1P$ strongly developed. On plates taken in the far ultra-violet under the same discharge conditions Werner finds his own bands, $A - C$ ($1^1S - C$), strongly developed, but if the Lyman bands, $A - B$ ($1^1S - B$), are present, they are very weak. The presence of the violet bands shows that the 2^1S states are formed; the weakness of the Lyman bands shows that they pass with difficulty into the 1^1S state, which is the only known deeper state. It looks as though they must get rid of their excitation energy by dissociating the hydrogen molecules with which they collide. The Lyman bands are present in the absorption spectrum of H_2, but they can only be excited efficiently in emission in presence of a large excess of argon. This will greatly reduce the opportunity of the excited hydrogen molecules to collide with other hydrogen molecules.

As regards the method by which I calculated B_0 (the band constant which is inversely proportional to the moment of inertia) for the 2^1S and 3^1P states, I used it because there was no other method available. I expressly stated that it was inaccurate in the data to which it had to be applied, and that the value obtained for the 2^1S state was likely to be too high. I now think that this error is due to some of the weaker lines being probably the wrong lines. Accepting Prof. Birge's value of about 28 for $2B_0$ for the 2^1S state, the second differences of the strong ${}_0A_0$ band in which the lines are probably trustworthy, show that the value 41 got by the same method for 3^1P was about right.

It is, at any rate, a cause for great satisfaction that there exists at the present time a complete harmony between the interpretation of the spectroscopic data for the molecule H_2 on one hand and the results of the theory of its structure according to the new quantum mechanics, as well as the theory of the specific heat of hydrogen, on the other. However, the last chapter of this story is not yet written. There are even now many important lines in the secondary hydrogen spectrum which are not understood and there may be room for some surprises still.

The Dominant Species of Ostrea.

In reviewing the characters of the dominant species of oysters, Ostrea, of which something is known of the life-history as well as the shell-characters, two distinct types are recognisable.

Type I. consists at present of

- *O. edulis*, Linn., the European oyster (see Hoek [1] and Dean [2]).
- *O. lurida*, Carpenter, the British Columbian oyster (see Stafford [3]).
- *O. Angasi*, Sowerby, the south-west Australian oyster (see Roughley [4]).

In this type the shell is sub-circular; the egg is large; the adult larviparous; the individual is hermaphrodite; spawning occurs at medium temperatures, round about 15° C.; and the species flourish in temperate regions.

Type II. consists at present of

- *O. virginica* (≡*elongata*), Gmelin, the American-Canadian oyster (see Stafford [3]).
- *O. angulata*, Lamarck, the Portuguese oyster (see Dean [2]).
- *O. cucullata*, Born, of world-wide distribution in sub-tropical and tropical parts (see Dean [5] and Roughley [6]).

In this type the shell is elongated in an antero-dorsal and postero-ventral direction; the egg is small; the adult non-larviparous; the individual of one sex only; spawning occurs at moderately high temperatures (round about 20° C.); and the species flourish in sub-tropical or tropical regions.

Although the species noted above are among the most abundant and most successful of the genus, a large number of other supposed species have been described (Sowerby [7])—from shell characters—at various times. Shell-characters are, however, now known to exhibit great range of variation within the species in the genus Ostrea, and it may be anticipated that in the—probably distant—future many supposed species will be found to be mere varieties. At present we are therefore confronted with a supposed large genus containing at least two well-defined groups of species amongst the best known and the most successful forms in the genus. These successful forms are, however, of such world-wide distribution that it is difficult for one individual to summarise into an accurate technical description the assemblage of characters occurring in the two types noted above.

It seems clear, nevertheless, that there is justification for recognising two groups of species, whether the groups be regarded as differing generically or only sub-generically. Type I. is clearly Ostrea, of generic, or type sub-generic value. while type II. may be regarded as Ostrea, sub-genus Gryphæa, or a separate genus, for which the name Gryphæa may be suggested, or a new generic name may be preferable, and Dioecioøstrea is a suitable one.

In a question of this kind international co-operation would be highly desirable in order to avoid overweighting of the literature with names. On the other hand, a decision must be made by someone, and if sufficient care be devoted to the matter it should be possible to avoid complications in the literature and at the same time give a better expression to the relationships of known forms than exists at present.

---

[3] Stafford, J., "The Canadian Oyster," 1913, Ottawa.
[4] Roughley, T. C., *Australian Museum Magazine*, 2, 1925.
[5] Dean, B., *Bull. U.S.F.C.*, 22; 1902 (1904).
[6] Roughley, T. C., *Proc. Linn. Soc. N.S.W.*, 1, 4; 1926.
[7] Sowerby, G. B., in Reeve's *Conchologia Iconica*, Part 288, 1871.

Similar cases do no doubt occur in all groups of plants and animals where international co-operation might be of value, if the machinery to effect it could be devised. But there is a danger, in such a method, of problems being shelved. For example, in 1912, attention was directed to the fact that the species of Cucumaria at Plymouth could be divided into two groups on such fundamental characters as the gross morphology of the gonad and presence or absence of radial symmetry, but the author forebore to establish a separate genus or sub-genus for one of these groups on the ground that such a proceeding would be better performed by a specialist reviewing the whole genus. That work is still waiting to be performed, and may not be done for several decades, whereas if the sub-genera had been created, the species of the genus would have been allotted to their proper place when revised locally or regionally.

Ideally, species of sub-genera should be phylogenetically related, but such relationships can rarely be established and are usually intelligent assumptions with a great probable error. There is always a possibility of convergence in evolution, especially in closely related forms, so that groups with certain characters in common may frequently comprise members which have not arisen unilaterally from a single common species or stock. Nevertheless, until the contrary is proved, the current method of grouping species with common characters into a sub-genus or genus—or even larger groups—will give a maximum first approximation value to phylogenetic relationships. Thus the practice of grouping similar species is defensible. One might in a case like the facies, Ostrea, go farther, and in an ideal scheme scrap the old names for new and more useful ones, such as, Monoeciostrea for Ostrea, type sub-genus, and Dioeciostrea for all such forms as conform with the characters of type II. noted above; at the same time, more useful names for the species might be obtained by latinising the now well-known common names, to give, for example:

O. edulis ≡ *Monoeciostrea europa*
O. lurida ≡ *Monoeciostrea vancouverensis*
O. Angasi ≡ *Monoeciostrea sud-australis*
O. virginica ≡ *Dioeciostrea americana*
O. angulata ≡ *Dioeciostrea hispaniola*
O. cucullata ≡ *Dioeciostrea subtropica*

A glance at the suggested new names is sufficient to show their superiority in descriptiveness.

The more the names of organisms describe their fundamental characters, the greater their value, and the nearer the approach to a simplified biology. The chief objection to descriptive names is, however, the constant inadequacy of extant knowledge. We never know that we know enough to describe organisms accurately for all time. For example, many animals are known to be functionally bisexual, or dioecious, but specifically hermaphrodite, or monoecious; and no doubt many other forms now supposed to be bisexual will be found in the future to be specifically hermaphrodite. Therefore, as we cannot expect to describe organisms for all time, we must expect and submit to change, but to avoid excess of change it is desirable that any effected change should be supported by either adequately proved individual or collective experience.

In the case of the two types of living species in Ostrea noted above, it is considered advisable to postpone the creation of new genera (with new or modified generic names) until more detailed information is available of their correlated morphological and biological characters. The names Monoeciostrea and Dioeciostrea are therefore mentioned merely as suitable types of names, and are not intended to be adopted in the literature until definition can be made, founded on adequate information. In the meantime, this discussion may stimulate inquiries into the characters of other less well-known species of the genus.

J. H. ORTON.

Marine Biological Laboratory,
Plymouth.

Soft X-ray Emission and Absorption Spectra with Tangential Grating.

SINCE 1925 I have endeavoured to apply, for spectrographic work in the domain of the X-rays, the ruled glass grating, used with very high glancing angle, approaching 90°, which is particularly suited to give a high resolving power. Successively, I obtained direct diffraction and absolute measurement of wave-length for an X-ray beam of $K\alpha$ and $K\beta$ of copper and iron (*C. R. Acad. Sci.*, Dec. 21, 1925), and showed that the same arrangement could be utilised for extreme ultra-violet spectra (copper condensed spark spectrum between 140 A. and 3500 A.) by adjusting the 'tangential grating' in vacuum (*Revue d'Optique*, 5, 97; 1926: *C. R.*, 182, 1141; 1926: *Journal de Physique*, Jan. 1927). Afterwards, using as the source of rays for the vacuum spectrograph a water-cooled metal X-ray tube and a glass grating with 30,000 lines to the inch from Prof. R. W. Wood, I have been able to obtain line spectra of soft X-rays (10 A.-100 A.) upon an ordinary photographic plate. The grating method seems, therefore, the most suitable to bridge the gap between the ultra-violet and X-rays (*C. R. Acad. Sci.*, 185, 62; 1927: *Journal de Physique*, Nov. 1927) (Fig. 1). Soltan and I have registered and measured the $K\alpha$ lines of boron (68·0 A.), carbon (44·9 A.), nitrogen (31·8 A.), oxygen (23·8 A.), the L spectrum of iron, the M lines of molybdenum (65·0 A., 54·9 A.), and a regular doublet ($\Delta\lambda = 3$ A.) from N series of heavier elements (for tantalum, tungsten, platinum, gold; lying between 46·8 A. and 61·4 A.) (*C. R. Acad. Sci.*, 185, 642; 1927: *Journal de Physique*, Dec. 1927, in which there are numerous reproductions of spectra).

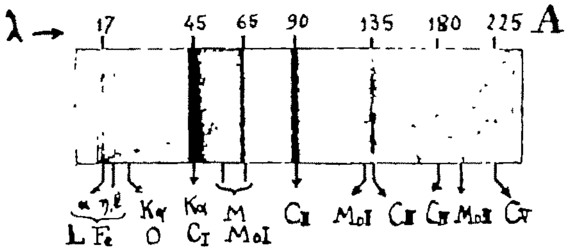

FIG. 1—Line spectrum.

In these earlier line spectra I have never noted the emission of a continuous radiation. Recently, however, using elements of high atomic weight as anticathode and intense electronic current in the tube (100 milliamp., 1000 volts), I have been able to demonstrate the emission of a continuous spectrum from solid bodies between 15 A. and 250 A. with similar properties to the independent background of a Coolidge tube.

The continuous background registered in my spectra is not uniform, but divided by a succession of fine bands with abrupt edges on the short wave-length sides (Figs. 2, 3). The absorption of soft X-rays, then, varies discontinuously whenever the frequency of the independent radiation reaches a discontinuity of atomic absorption of elements present in the path of the rays. The elements present in the vacuum spectrograph, at a pressure much less than a barye, are carbon (vapour from grease used in joints), nitrogen, and oxygen, and, in fact, we observe the intense K band of carbon (in five orders), and also of nitrogen and oxygen. It is hence a very sensitive method for revealing minute quantities of gaseous matter. The three absorption edges (carbon, nitrogen, and oxygen) are without structure, but seems limited by a 'white' absorption line similar to those observed close to the L edges of heavier elements (Nishina, Coster).

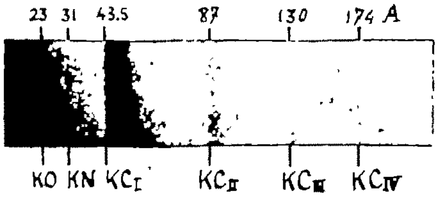

FIG 2.—Absorption spectrum

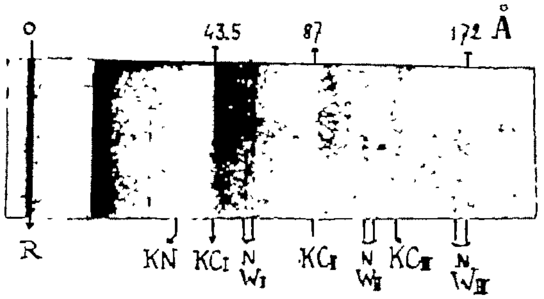

FIG. 3.—Emission and absorption spectrum.

The wave-lengths of the K edges are as follows:

	λ(A.).	V (volts).	ν/R.
Carbon (C) . .	43·5	284	21·0
Nitrogen (N_2) .	31·1	397	29·3
Oxygen (O_2) .	23·5	524	38·7

in good accordance with Holweck's results from the ionisation method.

The absorption spectra reproduced herewith are the first to be recorded by a photographic method in the gap between the ultra-violet and X-rays.

The Highly Penetrating Cosmic Rays.

IN their interesting account of new results on cosmic rays, published in the supplement to NATURE of Jan. 7, Prof. Millikan and Dr. Cameron direct attention to the statement made by Dr. E. Steinke (*Zeitschr. f. Physik*, **42**, 570; 1927) that the very careful measurements on highly-penetrating rays at sea-level performed by him do not show any real variations as to the intensity of these rays. I wish, however, to point out, as a matter of fact, that when the values of Dr. Steinke's measurements are arranged directly *according to sidereal time*, and when small systematic differences between the values of the different registering films are eliminated, these measurements show variations which are completely in accordance with those found by W. Kolhörster and G. von Salis (*Sitz. Ber. Preuss. Akad. d. Wiss.*, 11; 1927) and by K. Büttner (*Zeitschr. f. Physik*, **45**, 588; 1927), but are only in percentage smaller.

Although sidereal time shifts 50 minutes with respect to civil time during the thirteen days of Dr. Steinke's measurements, he has only computed the means and the mean errors for every hour of *civil* time (MEZ), and he regards these as valid also for sidereal hours. This may be excused in a careful experimental investigator who is not an astronomer, nevertheless it is evident that if we are seeking a possible correlation with respect to the sidereal time, the measurements must be arranged *from the beginning* according to this time. If we arrange the values in Steinke's Table 3 (where they are corrected for barometric effect) according to sidereal hours ($0^h = 23^h\ 30^m - 0^h\ 30^m$, *etc.*), and also according to the different registering films, we may first compute the means for every sidereal hour. Comparing, then, all values of a certain film with the corresponding last-mentioned means, we find the following systematic corrections for the films:

1926 Nov. 13-14 : − 0·022 volt/58^m
„ 15-16 : + 0·027 „
„ 16-17 : + 0·008 „
„ 17-18 : − 0·022 „
„ 18-19 : + 0·012 „
„ 19-20 : − 0·004 „
„ 20-21 : + 0·012 „
„ 21-22 : − 0·014 „
„ 22-23 : − 0·004 „
„ 23-24 : + 0·020 „
„ 24-25 : − 0·015 „

When we apply these corrections to the values of the corresponding films and then compute anew the mean, the mean error of every value, and the mean error of the mean for every sidereal hour, we find primarily that the means are very little affected by the systematic corrections. The weighted mean error of a single value is, however, here ± 0·0226 $V/58^m$ instead of ± 0·0295 $V/58^m$ as given by Steinke, and the weighted mean error of a point on the curve of the means is ± 0 0074 $V/58^m$ instead of ± 0·010 $V/58^m$ as given by Steinke. The curve shows the same maxima at 0^h, 5^h-7^h, 13^h-16^h, and 20^h (and in addition one maximum at 3^h), and the same minima at 4^h, 8^h-12^h, and 19^h sidereal time that were found by Kolhorster and Büttner (*loc. cit.*), and these extremes deviate about 0·016 $V/58^m$, or more than twice the mean error from the general mean (= 1·961 $V/58^m$ = 1·765 J cm.$^{-3}$ sec.$^{-1}$). Steinke's curve of the means for each hour of *civil* time agrees in some features with those of Kolhorster and Büttner, as was remarked by Büttner in his paper cited above.

As the curves of three authors, who have not only made their measurements at different times and places, and in different ways, but also hold different views, thus agree in the fundamental point of showing maxima and minima for the same sidereal times, and, moreover, greater percentage variations for increasing height over the sea-level, I think we must now consider the existence of these variations to be confirmed. The failure of Prof. Millikan's and Dr. Cameron's experiments to detect variations is puzzling and may have some unknown physical cause. I should like to suggest the possibility of the variations being caused mainly by somewhat softer cosmic rays (coming from the 'heated vacuum' of the Mira stars?—see *Astr. Nachr.*, 5529) than those found by Prof. Millikan and Dr. Cameron when their apparatus was sunk deep below the levels of the lakes used by them. In fact, the greater absorption coefficients (of Kolhorster) are found by such apparatus and experiments, which have also revealed great variations, whereas the smallest absorption coefficients are related to those experiments (of Millikan, Cameron, and Steinke), which show only small variations or none. In the mountain, or balloon, experiments, a mixture of both kinds of rays may have been measured. For full consideration of the lack of agreement of the measurements, it would, however, be most valuable if Prof. Millikan would, like the German workers, publish also the particulars of his measurements.

AXEL CORLIN.

Observatory, Lund,

The Relation of Specific Heat to Ferromagnetism.

FERROMAGNETIC substances, in addition to their purely magnetic qualities, have other properties which are distinctive. For example, the temperature coefficient of resistance and the thermo-electric power behave abnormally up to the critical temperature, and become approximately normal above this point. But notably the true specific heat shows abnormal behaviour with rise of temperature. It increases to a high value (C_θ) at the critical temperature, and then immediately above this temperature there is an abrupt change (ΔC) to a much lower value.

An equation connecting C_θ and ΔC, which is derived from observations on iron, cobalt, and nickel, is

$$m.a.C_\theta = 5n.a.\,\Delta C \quad . \quad . \quad . \quad . \quad (1)$$

where $m.a$ and $n.a$ are the molecular weights below and above the critical temperature, m and n being the number of atoms of atomic weight a in the molecule. Thus the molecular heat at the critical temperature is five times the molecular heat of the discontinuity, a result which is of significance. The discontinuity (ΔC) is intimately connected with two magnetic constants, the maximum intensity of magnetisation (I_θ) and the reciprocal of Curie's constant (R') as follows:

$$n.\Delta C.J.\rho = 278\ R'\ I^2_\theta \quad . \quad . \quad . \quad . \quad (2)$$

J and ρ being Joule's equivalent and the density of the material respectively.

Both equations are satisfied by the numerical values derived from experiments on iron, cobalt, nickel, and magnetite, and it is of interest and importance to inquire if the abnormal behaviour of the specific heat is always to be found with ferromagnetism, and if the magnetic constants have always a definite relation to the specific heat.

There is, fortunately, one other ferromagnetic substance on which experiments may be made for the answering of this question, namely, Heusler's alloy.

I am indebted to Prof. F. C. Thompson for a sample of this alloy with an analysis of it, and I have made a number of experiments on its properties. Briefly, it may be said that Heusler's alloy shows the same kind of abnormality with temperature in its thermo-electric power and electrical resistance as do other ferromagnetics. Further, the true specific heat increases rapidly up to the critical temperature and then exhibits a discontinuity such that the equation first given is satisfied, and also the maximum magnetic intensity and Curie's constant are related to the discontinuity of the true specific heat according to the second equation.

The specimen I have of Heusler's alloy has magnetic qualities which are similar to those of nickel. Its maximum intensity is 420, and its absolute critical temperature (θ) is 360° + 273, so that it conforms to the equation,

$$\frac{\theta}{I_0} = 8/27 \times q \quad . \quad . \quad . \quad . \quad (3)$$

where q is a whole number—the number 5—and it forms one of the whole number series 2, 3, 4, and 6, which are the q-values for iron, cobalt, nickel, and magnetite respectively. With Heusler's alloy, both C_θ and ΔC are, as with nickel, about half the values found in the other ferromagnetics.

Lastly, the alloy satisfies the general equation

$$\rho \cdot R_{mn} = R'\ I^2_0 \quad . \quad . \quad . \quad . \quad (4)$$

in which R_{mn} is the gas constant, if this is taken to be that of manganese with two atoms to the molecule.

Thus Heusler's alloy, like other ferromagnetics, conforms to the four equations given above which are characteristic of ferromagnetism, and the conclusion is that abnormal electric and thermal properties are necessarily associated with ferromagnetism, all of them being connected together by energy considerations.

Bird Feathers and the Antirachitic Vitamin D.

ON reading the article entitled "The Antirachitic Vitamin D" in NATURE of Dec. 31, which has just come to hand, it struck me that it might be worth while to record the following. In my student days I at one time kept various hawks and owls as pets. Many of these were taken from the nest and hand-reared, their food being in the main 'lights'—in the broadest sense—including liver. The majority died of rickets before attaining maturity. Among the exceptions were two favoured young tawny owls, which were fed almost exclusively on mice and sparrows. Success with these led me to add chicken heads complete with feathers and an occasional sparrow, also feathered, to the commissariat of the others. The only essential difference between the new diet and the old was the inclusion of feathers. The birds ceased to be troubled with rickets.

That feathers may be a source of vitamin D seems questionable in view of the general nature of a feather, yet birds possess nothing comparable with the sebaceous glands of mammals, and the so-called preen gland, practically the only skin gland known to occur in birds, is not present in all species. Many birds are entirely cereal eaters, except at such times as they are rearing young, which suggests that they may get their supply of vitamin D mainly from the solar radiation via their external covering of feathers. This need not necessarily mean through the substance of the feather, for most feathers have an oily coating. How much of this owes its origin to the preen gland is highly problematical, but so far as the gland itself is concerned, Prof. J. B. Collip tells me that he has found it to be rich in colesterol in the domestic fowl; and this may apply, and probably does, to feather oil generally, whatever its origin.

However, in view of these things, the following episode from the life-history of the merlin (*Falco columbarius æsalon*) seems worthy of note. As recorded in Pt. III. of my observations on this species in *British Birds* (Mar. 1922), another aspect of which drew comment in these columns (NATURE, Dec. 8, 1921, p. 478), the hen fed her chicks entirely on birds. These were nearly always brought to the eyrie plucked, the young being given the meat and less frequently the entrails, the bones as a rule being swallowed by the parent. The diet thus far compared excellently with the rickets-encouraging lights fed to my pet birds. But the growing merlins did not develop rickets, and it appears that the mother was 'aware' of the remedy, for from time to time she would bring in a victim entirely or partially feathered and feed mouthfuls of *feathers only* to all her offspring in turn. They quite evidently objected to it and regarded it as 'medicine,' for the mouthful invariably had to be thrust well down into the maw, and even then proved very difficult to swallow. Possibly it is true that there is nothing new under the sun, and we may here be witnessing a crude method of administering the antirachitic vitamin D that has, no doubt, been in practice for countless centuries.

The Cause of Fishiness in Dairy Products.

The action of Fenton's reagent (hydrogen peroxide in the presence of small amounts of ferrous salt) on lecithins in alcoholic solution causes the oxidation of the choline and amino-ethyl alcohol portions to trimethylamine and methylamine respectively (together with some ammonia).

The olein of butterfat, owing to its unsaturation, easily absorbs oxygen to form a labile peroxide, the absorption being strongly catalysed by compounds of heavy metals, especially those of copper. The peroxide thus formed is an active oxidising agent in fatty media and is also a catalyst to more advanced oxidation. Lecithin is intimately associated with the fat peroxide in the fat phase of dairy products, and its nitrogenous base portion is oxidised through the agencies of the fat peroxide and the catalytic activity of the metallic (copper) compounds present, forming volatile bases possessing a fishy odour. That is, the reaction involved is a modified Fenton reaction in the fat phase. These volatile bases (trimethylamine mostly), together with the easily hydrolysable salts of these bases with free fatty acids (butyric and oleic), are the causes of fishy flavours and smells in dairy products.

The importance of small amounts of metallic compounds, copper especially, in strongly catalysing the oxidation must be realised, since, without metallic contamination, the formation of labile peroxide would be slow, and, since rancidity is a precursor to fishiness, that degree of rancidity necessary for fishiness to develop would not have been reached during the normal storage of products free from metallic contamination. In the examination of all products which were fishy, copper in appreciable quantity has been found to be present.

That such oxidation is possible in butterfat also demonstrates the need of inquiry into the fate of fat-soluble vitamins during the development of rancidity.

Nomenclature of Eruptive Rocks.

The reviewer of my book "Eruptive Rocks" (Nature, Dec. 17, 1927) says that I have not accomplished my expressed purpose of cleaning up "the jungle of rock names." The *wisdom* of my procedure is open to question, but the *facts* can be ascertained by simple enumeration. Prof. Arthur Holmes collected about 470 names of eruptive rocks in his "Nomenclature of Petrology," and the total number in use at the present time is certainly not less than 500. Of these I have used only 56 in my system, a reduction of about 88 per cent. This seems to me to be a fairly thorough 'cleaning-up,' and I wonder what more the reviewer wants? Of course, I use some qualifying terms in conjunction with these names, but so does every petrologist, no matter what system he follows.

S. J. Shand.

University of Stellenbosch,
Jan. 11.

Prof. Shand has been led astray by his metaphor. He imagines that petrographic nomenclature is to be cleaned up by the simple process of chopping down names to the extent of 88 per cent. (as he claims), just as a jungle would be cleaned up by chopping down trees and clearing undergrowth. In denying that he has cleaned up the jungle of rock names I merely meant to imply, following his metaphor, that he has not, in my opinion, succeeded in his task of reforming petrographic nomenclature. I do not deny that he has eliminated, or attempted to eliminate, a large number of rock names, some desirable, others undesirable; but he has also added a number of fungoid growths such as per-, sub-, meta-, -oid, to the names he has spared, a procedure which, in my opinion, neither lessens the confusion nor contributes to the beauty of the nomenclatorial jungle.

It may further be questioned whether Prof. Shand has really cleaned up the jungle to the extent of 88 per cent. Of the 470 igneous rock names given in Holmes's "Nomenclature of Petrology," probably at least half have never been used more than once, and are, therefore, seeds that never took root.

The Reviewer.

Mammoths and Man in the Transvaal.

In the supplement to Nature of Dec. 10 is an interesting contribution by Prof. Dart on "Mammoths and Man in the Transvaal." The paper is valuable in directing attention to the importance of the Vaal River diamond gravel terraces, and the light which they will probably throw on early man in South Africa, and possibly on the wild animals associated with him. Whether Prof. Dart's conclusions are confirmed or not, the paper will result in more intensive work being done. Some of us who for years have been interested in the matter, have come to conclusions which differ from those of Prof. Dart.

Two years ago Miss Wilman, director of the Kimberley Museum, sent to Prof. Osborn, at my suggestion, two elephant teeth from the gravels of Barkly West. These Prof. Osborn determined as two species of Archidiskodon, one of which he regarded as a Middle Pliocene type and the other as an Upper Pliocene or Lower Pleistocene type. Three years ago I described the molar of an extinct giant pig from another gravel deposit. At present I have on hand four specimens collected by diggers, evidences of a huge extinct horse, and of a second type of large pig. All these teeth show some signs of being water worn, and if Prof. Osborn is right in regarding the elephant teeth as of Pliocene or Lower Pleistocene type, we must conclude, I think, that the teeth have been carried into the deposit from a much earlier one. If, as seems probable, Prof. Dart's Archidiskodon teeth are similar to those examined by Prof. Osborn, then it may be regarded as almost certain that they are very much older than the lowest gravels of the Vaal, which cannot be of great geological antiquity.

The Influence of Diet upon the Teeth.

OWING to the prevalence of dental caries under our present conditions of living and dieting, knowledge of its cause, and the means by which it may be prevented or its ravages mitigated, is of great importance not only to the individual but also to the nation. During the last decade, attention has been directed by a number of observers to the influence which various types of diet may exert upon the structure of the teeth, often in conjunction with their effects upon other tissues of the body, especially the skeleton. This work has demonstrated that diet plays an important part in producing abnormalities of the teeth of experimental animals: the relationship of these abnormalities to dental caries is not so clear, since animals comparatively rarely suffer from this type of dental disease. Some evidence has been produced that there is a definite relationship between the structure of the teeth and caries, but it has not met with universal acceptance. In this article the influence of diet upon the structure of the teeth will be more especially considered, and the problem of dental caries only mentioned incidentally, where it appears to throw light upon the manner in which diet may affect the teeth. To illustrate the points raised, reference will be made to a few of the more recent papers dealing with the subject: further details will be found in these papers and also in those mentioned in their bibliographies.

There appear to be three ways in which diet can affect the teeth: food lodged in their crevices may undergo changes which lead to alterations in the enamel and other structures of the tooth; the diet may alter the composition of the saliva and thereby affect the teeth indirectly; or it may alter the structure of the tooth directly, in a comparable manner to its effect upon other tissues of the body. In the first two cases the agent acting upon the teeth attacks them, so to speak, from their outer or superficial surface; in the last, the changes depend upon an alteration in the composition of the blood and lymph reaching the tooth, and are thus initiated from the pulp or from within the tooth itself.

There is probably general agreement that caries is initiated by the fermentation of carbohydrate food stagnating between the cusps of the molar teeth, between the teeth themselves, and round their necks. According to J. Sim Wallace (*Med. Press and Circ.*, vol. 124, p. 487; 1927), diet cleanses the teeth mechanically, by initiating the secretion of ptyalin and by controlling the bacterial flora which digests remnants of food remaining between them. Efficient mastication is necessary both for keeping them clean and for ensuring their proper development together with that of the jaws. Inefficient mastication, leaving stagnating mucus on and around the teeth, encourages the development of tartar, since bacterial decomposition of the mucus leads to the production of alkali and the consequent precipitation of certain salts. On the other hand, the consumption of soft, sticky carbohydrate food leads to the production of acid, from the bacterial decomposition of the masses adhering to the crevices of the teeth, and this acid attack the interprismatic areas of the enamel, initiatin caries. Thus starchy or sugary foods favour th development of caries, whilst the more fibrous foods such as fruits or raw vegetables, and fish and meats tend to cleanse the teeth both mechanically and b increasing the secretion of saliva which washe away adhering remnants, and thus hinder or preven dental decay. Experiments have shown that acid forming bacteria can initiate caries when grow *in vitro* in the presence of teeth, the acid attackin the enamel: at least two organisms have bee found in or on carious teeth which can form aci from carbohydrate, but whether either of them i specific for this disease is not yet certain. Penetration of the enamel is very slow unless the acidit is of the order of pH 5·0 (I. H. Maclean, *Proc. Ro Soc. Med.*, vol. 20 (Sect. Odont.), p. 873; 1927).

Little is known about the possibility of alterin the composition of the saliva by changes in the diet Although saliva is a secretion, it is possible tha certain changes in the composition of the blood ma be reflected in this secretion: in health, the variations in the different constituents of the blood li within very narrow limits, but they are more marke in disease, and variations from the average norma might then be observed in the composition of th saliva. In fact, C. L. Pattison has found definit changes in the calcium with variations in the die (*Brit. Med. Jour.*, vol. 2, p. 6; 1926). The wor was carried out on children suffering from tuberculosis of the bones and joints. On admission t hospital the average salivary calcium was 4·77 mgm per 100 c.c. On the ordinary hospital diet this ros to 7·79 mgm.; on a diet containing little milk, n cod-liver oil or eggs, but oatmeal and olive oil, th figure was almost unchanged (4·68 mgm.); but whe plenty of milk and cod-liver oil and an egg, but n oatmeal, were given daily, the salivary calcium ros to 10·68 mgm. per 100 c.c. In the light of our presen knowledge, there is little doubt that these resul are to be explained by the improvement in absorption and retention of calcium which occurs on th administration of adequate amounts of vitamin D following a relative or absolute deficiency in th intake of this compound. Addition of a calciu salt to the diet for a short period was without effe on the salivary calcium. Whether changes in th composition of the saliva can influence the teeth not known: a possible indirect effect might b suggested by means of subsequent alterations in th bacterial flora of the mouth.

It is now known that the structure and composition of the teeth can be affected by changes in th amounts of calcium and phosphorus and of vitamin C or D in the diet: in general, it may be said tha the proper development of the teeth usually show a close relationship to the proper development the bony skeleton. In producing imperfect calcification and structure of the teeth, deficient intak of calcium or phosphorus, or an improper rati between these two elements in the diet, has mos often been associated with a deficiency of vitamin D also. J. A. Marshall, however, found that pups exposed to sunlight and kept on a diet containing an adequate amount of vitamins, but with improper quantities of calcium and phosphorus, developed gross changes in their teeth, including imperfect calcification of the enamel and relative absence of the dentine: there was marked delay in dentition, and the deciduous teeth were not shed (*Jour. Amer. Med. Ass.*, vol. 81, p. 1665; 1923). G. Toverud also observed that in white rats maintained on a diet deficient in calcium the teeth contained less mineral ash than normal teeth (*Jour. Biol. Chem.*, vol. 58, p. 583; 1923); whilst M. R. Jones and F. V. Simonton found that the addition of alkali (sodium carbonate) to a diet complete in every other respect produced changes in the teeth and jaws of puppies (*Proc. Soc. Exper. Biol. and Med.*, vol. 23, p. 734; 1926). It is known that the absorption of calcium and phosphorus is influenced by the hydrogen ion concentration of the contents of the intestine, alkali interfering with this absorption and acid increasing it. C. J. Grieves (*Jour. Amer. Med. Ass.*, vol. 79, p. 1567; 1922) also found that a deficiency of calcium in the diet increased the amount of dental caries in the teeth of rats. Decay also occurred when the calcium was increased above the optimal amount: thus the effective factor appeared to be an improper calcium-phosphorus ratio rather than a simple change in the amount of calcium alone.

Among the symptoms of scurvy, due to deficiency of vitamin C in the diet, are hæmorrhages in various parts of the body, including the gums, in which situation they are accompanied by a loosening of the teeth in the jaws. Experimentally, changes in the teeth have been described by several authors: P. R. Howe (*Jour. Amer. Med. Ass.*, vol. 79, p. 1565; 1922), has observed decalcification of guinea-pigs' teeth, when the animals were kept on a scorbutic diet, with recalcification when a source of vitamin C, such as orange juice, was added to the food. Dental caries was present in the animals on the faulty diet. F. M. Wells (*Proc. Roy. Soc. Med.*, vol. 12 (Sect. Odont.), p. 22; 1919) and Toverud (*loc. cit.*) have described changes in the pulp of the teeth of scorbutic guinea-pigs with replacement of the orthodentine by osteodentine: the degeneration of the pulp may occur before other clinical signs of scurvy are present.

Probably the most important factor in producing alterations in the teeth is a shortage of vitamin D, or the antirachitic vitamin, with or without accompanying defects in the diet, such as variations in the calcium-phosphorus ratio. E. V. McCollum and his collaborators described changes in the teeth of rats maintained on diets low in protein, calcium, and fat-soluble vitamins (*Bull. Johns Hopkins Hosp.*, vol. 33, p. 202; 1922), and Grieves (*loc. cit.*) found that caries was worse in rats when the diet was deficient in fat-soluble vitamin as well as calcium than when it was deficient in calcium alone. In puppies, May Mellanby has shown that the most important variables affecting the formation of the teeth are variations in the amount and type of cereal in the food, in the amount of fat-soluble vitamin present, and in the degree of exposure of the animals to ultra-violet light (M. Mellanby, *Proc. Roy. Soc. Med.*, vol. 16 (Sect. Odont.), p. 74; 1923, etc., summarised by E. Mellanby, *Brit. Med. Jour.*, vol. 1, p. 515; 1926). The less vitamin and the more cereal present in the diet, the worse was the structure of the teeth. When the bitch was fed on the deficient diet during pregnancy and lactation, the deciduous teeth of the pups were affected; if the latter were given the diet after weaning, the defects were disclosed in the permanent teeth. It thus seems possible that the influence of carbohydrates upon dental caries is not only due to their fermentation in the mouth, but also to their effect, in association with the fat-soluble vitamin, and after their digestion and absorption, upon the structure of the teeth.

How far are these results applicable to human beings? It is beyond the scope of this article to discuss the relationship between the structure of human teeth and dental caries, but it may be mentioned that May Mellanby has adduced evidence of a close relationship between defective structure and caries, based on the microscopic examination of a large number of teeth. Discrepancies are explained as due to alterations in the structure of the teeth after they have erupted. That the defective structure is due to deficiencies in the diet is possible but unproven, since the diets of the patients from whom the teeth were obtained were not known or regulated; but where it has been possible to control the diet, a definite relationship between it and the spread of caries has been observed. About thirty children in an institution were divided into three groups, and each group given a carefully selected diet (May Mellanby, C. L. Pattison, and J. M. Proud, *Brit. Med. Jour.*, vol. 2, p. 354; 1924). Careful examination of the teeth was made at the beginning and end of the experimental period of seven to eight months, and the general condition as regards defective structure and the position and extent of caries noted. One of the diets was the ordinary hospital diet: on this the average number of teeth per child in which caries had spread was 2·9; on a diet containing less milk and no butter, but more oatmeal, *i.e.* low in calcifying vitamin (vitamin D) and calcium, the spread of caries was represented by 5·1 teeth becoming more affected in each child; whilst on a diet containing more milk and no oatmeal, *i.e.* abundant vitamin D and calcium, the figure was 1·4 only. Thus there appears to be a close relationship between the diet and the spread of dental caries in human beings.

More recently, May Mellanby has published some work on the structure of human teeth, the results of which suggest that diet plays an important part in producing defects of structure (*Brit. Dental Jour.*, July 1, 1927). More than 1000 deciduous and more than 250 permanent teeth were examined both macroscopically and microscopically: in many cases the first examination was made whilst they were still in the mouth. The results obtained depend, of course, upon the definitions of the terms 'normal' and 'abnormal' as regards tooth structure. Descriptions are given of the naked-eye appearance of the enamel in various degrees of hypoplasia, and of the microscopic picture of the dentine: any uncalcified areas in the dentine are considered to be abnormal, but are so common that it is possible some authorities would consider them normal. Close agreement between the macroscopic and microscopic appearances was obtained in more than 85 per cent. of the examinations. Of the deciduous teeth, 14 per cent. were found to be perfectly calcified, 21 per cent. were slightly, and 64 per cent. definitely, hypoplastic. The incisors were the best calcified, 49 per cent. being normal: 8 per cent. of the canines, 7 per cent. of the first molars, and only 1 per cent. of the second molars could be so classed. Slighter defects appeared among the remaining incisors and canines, and the more severe degrees of hypoplasia were observed in the majority of the defective molars. The teeth obtained from private sources, as opposed to those from dental clinics, were less defective in structure. Of the permanent teeth examined, none was normal, and 92 per cent. showed definite hypoplasia; but these figures give no indication of the condition of permanent teeth in Great Britain, since all those examined had been extracted for caries, or to help in the adjustment of irregularities.

These results also indicate that there is less chance of interference with calcification before birth than afterwards, and that the more rapid the development of the tooth, the more defective is its structure likely to be. The defects in structure are probably to be correlated with the diet during the time the teeth are developing in the jaws: thus before birth, even if the mother is on a deficient diet, the fœtus can obtain its requirements of salts and vitamins by the sacrifice of the maternal stores. After weaning, the child has to depend entirely on its food and on its own stores, which are likely to be low if the mother's diet has been poor, for its supply of the substances necessary for the proper development and calcification of the teeth. At the same time, the diet frequently contains a large amount of cereal products, the influence of which is exerted against proper calcification. The incisors are the most advanced in development at birth, and are also the best developed structurally. The second molars are the least developed at birth; they grow rapidly after birth, and have the worst structure of any of the teeth.

In conclusion, it may be said that diet affects the teeth as it affects the other tissues of the body, and that the teeth, like the other tissues, respond more easily to some defects in the diet than to others, but that the same defect rarely affects more than a few of the tissues to a marked degree. In addition, the diet can affect the teeth locally by causing alterations in their environment, the changes in the teeth then starting from their oral surfaces.

The degree to which diet directly affects the structure of the teeth depends in part on the definition of the terms 'normal' and 'abnormal' as regards this structure: and on this depends again the relationship between abnormality of structure and dental decay. In any case, caries will not be initiated unless acid is present on the oral surfaces of the tooth. It may be pointed out that it is difficult to produce caries in animals unless at the same time the conditions are such as to lead to defective structure also.

The Enhancement Principle in X-ray Photographs.

By Sir WILLIAM BRAGG, K.B.E., F.R.S.

AN interesting phenomenon is often shown in the X-ray rotation photographs of crystals. Photographs of this kind are obtained by causing a crystal to revolve steadily about an axis perpendicular to the direction of a fine pencil of homogeneous X-rays. As the crystal revolves, one set of planes after another comes to a favourable condition for reflecting the pencil and a corresponding spot appears upon the plate. The crystal is usually very small indeed, and the shape of the crystal largely determines the form of the spot. The complete photograph shows an array of spots which displays certain regularities of arrangement as exemplified in Figs. 1, 2, and 3. When the photographic plate is flat, the spots arrange themselves on hyperbolæ as in Fig. 1; if a circular film is used the hyperbolæ are replaced by straight lines as in Figs. 2 and 3. The phenomenon to which attention is now directed consists in the enhancement, sometimes a very great enhancement, of certain groups of the spots. The explanation is more readily understood if consideration is first given to an analogous case of greater simplicity.

An ordinary optical grating gives a series of spectra: if the incident light is homogeneous, each spectrum is limited to a line. If now every fifth line in the grating were intensified or altered in some way, there would be added to the series already referred to a second series consisting of lines five times as close-packed, and every fifth line of the new spectrum would coincide with one of the old. For the sake of what follows, this may be put in another way.

If, in the first place, the grating had contained only lines corresponding to those which we have spoken of above as being intensified in some way, the more numerous series of spectra also referred to above would have appeared upon the plate. If, now, four other lines were intercalated uniformly between the lines already drawn upon the grating, every fifth line of the series of spectra would be enhanced.

From this simple case we may now proceed to the more complicated three-dimensional case of the crystal. A first example may be taken from the work on the structure of the silicates which has been carried out by Prof. W. L. Bragg and his colleagues at Manchester They have shown that a silicate may be regarded in the first instance as a compilation of close-packed spherical oxygen atoms: the other atoms belonging to the silicate are to be thought of as inserted in the interstices in the close-packed structure. Sometimes the inserted atoms, for example, when they are beryllium or silicon, do not strain the structure, and again larger atoms such as calcium or magnesium distort it more or less. But in all cases the silicate structure may be described as consisting of a basis of close-packed oxygens on which a larger pattern of other atoms has been superimposed. This is the very condition which was exemplified in simpler form in the optical case already described. When the rotation photographs are considered, the parallel consequences are also to be found. Certain spots are strongly enhanced; these are the spots which would be given by the oxygens acting alone in close-packed structure. The multiplicity of other spots which fill the photograph, including those which have been enhanced, are such as would appear if the structure consisted only of all the atoms except the oxygens. An example of these photographs was given in NATURE, Sept. 17, 1927, and is reproduced here (Fig. 1). This one picture is sufficient to show the exceedingly interesting and beautiful structure of the silicate family.

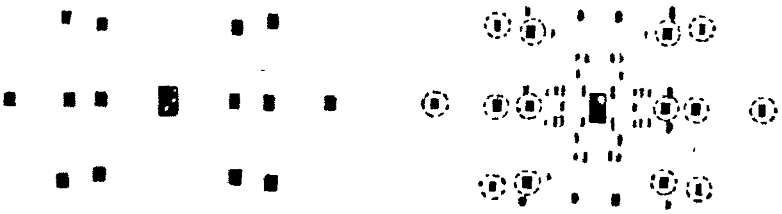

FIG. 1.—Rotation photograph around *b*-axis of disthene (right) compared with ideal rotation photograph around cube edge for close-packed atoms (left). Spots in the right-hand diagram corresponding to spots in the left-hand diagram are contained in circles.

A second example may be taken from the work of Dr. Müller on the long chain compounds (*Proc. Roy. Soc.*, vol. 114, p. 542). In this case also there are two periodicities in the structure. There is that which depends on the length of the chain, which in stearic acid is 48·84 A. Along the axis of the chain there is a second and finer periodicity due to the regular arrangement of the carbon atoms. The repetition takes place every second atom and its length is 2·52: the one periodicity is approximately nineteen times that of the other. A rotation photograph of stearic acid shows a multiplicity of spots due to the many sets of planes which are capable of reflecting the homogeneous X-rays usually employed. Some of these spots are very strongly enhanced for similar reasons to those already given. For example, the sets of planes denoted by (2, 0, 19), (2, 0, 38), (0, 1, 20), (0, 2, 19), (0, 3, 19), (0, 0, 18), (0, 0, 20), all show up on the plate, and indeed are almost the only high indices planes to appear. Such sets divide the *c*-axis into 18, 19, 20 . . . equal parts, as their designation implies. Consequently, their periodicities nearly coincide with that of the carbons of the chain. It is not necessary that the one periodicity should be an exact submultiple of the other.

A third example may be taken from the photographs of naphthalene and anthracene about the *c*-axis. It will be seen from a comparison of the two accompanying illustrations (Figs. 2 and 3) that whole rows of spots are here enhanced. Proceeding upwards or downwards from the central horizontal row, which is called the equator, the first row in each case is still strong; but in naphthalene the second row almost fails, and in anthracene the second and third. There is, in fact, a maximum between the third and fourth rows in naphthalene and the fourth and fifth rows in anthracene. The succeeding minima of intensity of rows are not shown in these pictures, because it is somewhat inconvenient to obtain photographs sufficiently extended upwards and downwards to include them, but it is easy to find out from other observations, which need not be given here, that minima do follow and are succeeded again by maxima. Thus, for example, the eighth and ninth rows of anthracene are strong. This enhancement of whole rows means that there is a certain repetition along the *c*-axis of a distribution of matter which in the case of naphthalene divides it into between three and four

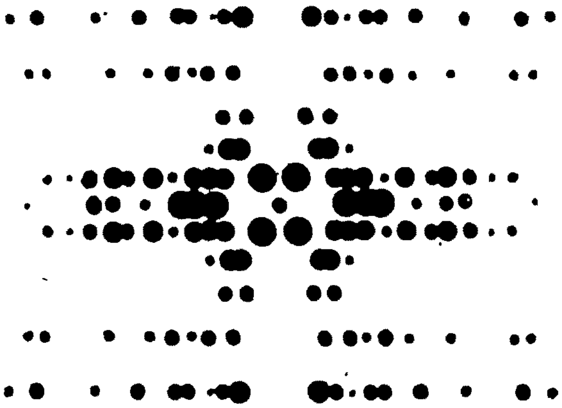

FIG. 2.—Rotation photograph about the *c*-axis of anthracene. The size of a spot is intended to represent its strength on the photographic film.

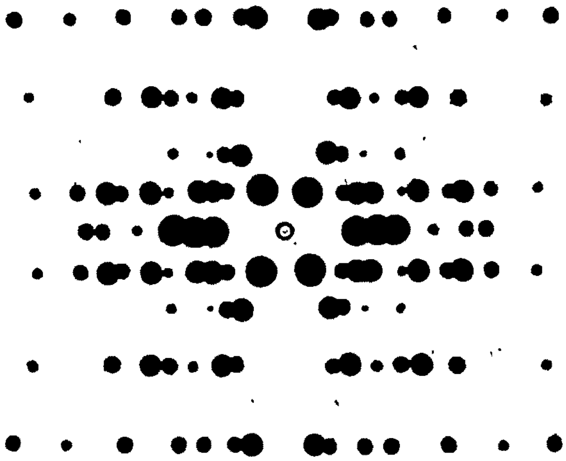

FIG. 3.—Rotation photograph about the *c*-axis of naphthalene.

parts; in the case of anthracene, between four and five. This is just what is to be expected if the structure of these crystals is that which was given by the author some years ago. The axis of a crystal in each case lies along the *c*-axis and the repetition is of the width of a benzene ring, namely, 2·52. The length of the *c*-axis of naphthalene is 8·69 and of anthracene 11·18. The axis of the former case is 3½ times the width of the ring, and of the latter case about 4½ times. The enhancement of the ninth row is due to the fact that the diameter of the ring divides it into two equal halves; there are periodicities of both 1·26 and 2·52 along the *c*-axis. The distribution of the intensities of the various lines in these figures is, in fact, an index of the distribution of matter or electrons along the axis about which the crystal was rotated.

There is one further point of interest in these last photographs. It will be observed that the distribution of spots on the equator is exactly the same for the two crystals. Even in the next row there is very little difference for the two, though the difference increases with the distance of the rows from the equator. Assuming the structure of the crystals to be that already referred to, to an eye looking along the *c*-axis the crystals would seem exactly alike. To what may be called to an X-ray eye looking in the same direction the crystals would look very nearly alike, but there would be a small difference because such an eye would see in depth as well as in plan. The eye would not observe, and the X-ray eye would, that certain atoms were hiding behind one another. The spots on the equator are due to planes which pass through the *c*-axis. The very close correspondence between the positions and intensities of the equator spots in the two crystals shows that to an eye, supposed capable of looking along the *c*-axis and observing the disposition of the atoms, the two crystals would appear exactly the same. This is confirmatory evidence of the structures assigned to them.

A somewhat different use of the same principle has been made by W. T. Astbury in his work on the acetyl-acetones (*Proc. Roy. Soc.*, **112**, p. 457). From a consideration of the relative intensities of the rows, he has drawn conclusions as to the relative positions of the molecules in the unit cell of the crystal.

Obituary.

Mr. Alexander Siemens.

Alexander Siemens was born in Hanover in January 1847. He belonged to the second generation of the four brothers Siemens whose names are so well known. He used to tell how his parents owed allegiance to the King of England until 1837, when, under the Salic Law, Hanover was separated from England and given to the Duke of Cumberland, the fifth son of George III. In 1866 Hanover was annexed by Prussia, and Siemens automatically became a Prussian. He was educated at Hanover and Berlin, and in 1867 entered the telegraph workshops of Siemens' Brothers at Woolwich, of which Sir William Siemens, the first president of the Institution of Electrical Engineers, was a director. He was then employed in the erection of the Indo-European telegraph line in Persia and in laying cables in the Black Sea. He also worked in the cable ship *Faraday*. He served in the German Army during the Franco-Prussian War and was awarded the Iron Cross. In 1878 he became a naturalised British subject.

After his release from the German Army, Siemens came to England and assisted Sir William Siemens in developing the regenerative furnace. About 1879 he developed a system of lighting public halls by means of arc lamps. The systems adopted at the Albert Hall and in the British Museum Reading Room were done under his direction. He also carried out the electric lighting of Godalming, the first town in England to have an electric-light supply.

Siemens had the greatest faith in science, in scientific training, and especially in scientific management. He considered that scientific management was quite as important as either capital or labour in developing the industry of the country. He was enthusiastically in favour of the decimal system, and in 1902 strongly advocated its universal adoption in a discussion held at the Institution of Electrical Engineers. His great protagonist was the late Sir Frederick Bramwell. The sympathies of most of the auditors were in favour of the decimal system, but the older generation of engineers seemed to think that engineering in Great Britain would be hopelessly handicapped internationally were we to abolish the inch and the pound. There was one thing said at this meeting which the writer never saw contradicted, and that was that without the decimal system it would not be possible to extract square roots. It is quite easy, however, to turn the square root of any number or fraction into a continued fraction and then find its value to any required degree of accuracy as a vulgar fraction.

Siemens was president of the Institution of Electrical Engineers in 1894 and 1904, and of the Institution of Civil Engineers in 1910. In his presidential address in 1894 he discussed, among other subjects, the possibility of trebling the speed of our trains. Although he considered it rash to say that such a speed could not be obtained, yet the necessity of strengthening the permanent way, etc., made it very unlikely that it would be adopted commercially. He contributed many papers and gave many lectures to scientific bodies. One of his most interesting papers was an account of experiments carried out by German engineers on the military railway connecting Marienfelde and Zossen. In these experiments, train speeds up to 125 miles per hour were obtained. The A.E.G. Co. insured the lives of their engineers before the experiments. After the tests, the front of the engine was coated with dead insects, and amongst them a dead swallow. The speeds attained seem small now, but twenty-six years ago they excited the greatest interest. The writer remembers also how Siemens showed that the empirical formula found by the German engineers for the air resistance was in almost exact agreement with that obtained by Sir Isaac Newton.

Alexander Siemens was a member of the committee which in 1897 discussed the desirability of establishing a National Physical Laboratory in Great Britain. Later on he served on the executive council. He married in 1881 Frances Dodwell, of Campden, Gloucestershire, and had three daughters, the eldest of whom married the late Prof. Bertram Hopkinson, of Cambridge. For many years Siemens used to attend the Council dinners and meetings of the Institution of Electrical Engineers, and his kindly nature and interesting conversation made him many friends.

A. R.

Col. S. W. H. Rawlins.

Col.-Commandant Stuart William Hughes Rawlins died on Dec. 16 last, from acute pneumonia, near Aldershot, where he commanded the artillery of the 2nd Division. Born in 1880, Rawlins' name was on the list of successful competitors at the 1893 election of scholars at Eton. His family tradition was closely bound up both with Eton and with academic life. His father, William Donaldson Rawlins, was a life fellow of Trinity College, Cambridge. His uncle, Francis Hay Rawlins, became lower master and ultimately vice-provost at Eton, and was one of the last fellows of King's under the statutes by which a fellowship was retained for life. Leaving Eton rather sooner than many boys, Rawlins went into the Royal Marines, in which he saw five years' service and from which he transferred to the Army.

During the years before the War, apart from fighting in South Africa, Rawlins saw much foreign service, chiefly in India and Central Africa, an experience which gave him every opportunity of indulging his naturally great linguistic powers. He could converse in numerous dialects, chiefly of Swahili. His taste for languages was coupled with an active interest in ethnology and archæology, add to these considerable musical sympathy, and it is clear that Rawlins, even outside his professional skill, was no common person.

To the scientific reader, the feature of greatest interest in Col. Rawlins' career is no doubt his association with the chemical warfare organisation in Great Britain as Commandant of the Experimental Station at Porton. Porton, from consisting of two or three huts at the commencement of 1917, underwent remarkable development under the direction of the late Dr. (Lieut.-Col.) A. W. Crossley, so that before the date of the Armistice it consisted of numerous departments and employed more than six hundred persons. Its activities then were chiefly on the offensive side. Parallel with Porton, the late Lieut.-Col. E. F. Harrison developed, first at Millbank and later at University College, London, the extensive organisation which in the first three months of 1918 manufactured three million respirators. The Navy had its own organisation. With the Armistice, the activities of these stations were suspended, and remained so until the Cabinet was able to define its international obligations.

Towards the end of 1920, the present Chemical Warfare Committee was formed, and at the start the whole of its experimental work, focused on defence, was concentrated at Porton, to the command of which Col. Rawlins was appointed on Aug. 29, 1921. From that date until he left to become Director of Artillery in November 1924, Rawlins with untiring energy bent his great mental powers to the development of the station. Many a soldier in his place would have regarded the appointment as a purely military one and would have left the scientific side entirely to his technical experts. Not so Rawlins. He made up his mind to understand the activities of each department and to be able to contribute intelligent constructive criticism to the scientific reports over which his name appeared. So successful was he that when ill-health overtook the director of experiments, Rawlins himself largely filled the gap. Porton having become the Experimental Station not only of the Army but also of the Navy, Rawlins' early years of training in the Royal Marines gave him a practical knowledge of the naval point of view which was of great value. On the technical side, Rawlins had the unique qualification of having served in the War as right-hand man to Sir Noel Birch, who was chief artillery adviser at G.H.Q. during the latter years of the War. Rawlins therefore had complete knowledge of the requirements of the Army in all that pertained to smoke and gas.

Of Rawlins, Sir Noel writes: "He was a master organiser, as proved by his work at the War Office," that is, during his tenure of the office of Director of Artillery.

Rawlins' high intellectual equipment, his varied experience, and his untiring power of work would not by themselves have sufficed for the solution of many of the problems which beset Porton. His success was in great measure due to his personality. Full of vigour, full of hope, full of cheerfulness, full of generosity, full of helpfulness, Rawlins attached friends to himself from all walks of life, and, aided in full measure by his wife, he has left a community in every locality in which he has been stationed who cherish a thousand memories of his devotion.

We regret to announce the following deaths:

Mr. Martin J. Cole, part author of "Modern Microscopy" (Cross and Cole) and an expert on the preparation of microscope specimens, on Feb. 8, aged eighty-one years.

Prof. Willis L. Moore, professor of applied meteorology at George Washington University and an honorary member of the Royal Meteorological Society, on Dec. 18, aged seventy-one years.

Sir Dawson Williams, who retired in January last from the editorship of the *British Medical Journal* after thirty years of distinguished service in that office, on Feb. 27, aged seventy-three years.

News and Views.

CHAULMOOGRA oil is an old drug in the treatment of leprosy, but it is only in comparatively recent years that a really useful remedy has been evolved from it. Long trials and experiments by Manson, Roux, Heiser, Rogers, and others have culminated in 'alepol,' a preparation of sodium hydnocarpate suitable for injection, and from the account given by Sir Leonard Rogers at the annual meeting of the British Empire Leprosy Relief Association on Feb. 24, it seems that it is possible with this to achieve a cure or something very near a cure in a sensible proportion of cases, especially if treatment is commenced at an early stage. Renewed interest in leprosy and its intensive investigation has also shown that the disease is more prevalent in Great Britain and elsewhere than had been supposed, and the Association has a considerable task before it. Besides surveying the problem, it has distributed the remedy on a large scale, and has provided seeds of the plant (*Taraktogenos kurzii*) from which the oil and ultimately the separated gynocardic acid is prepared, so that the drug may be grown locally in the various foci where it is needed. No one should imagine that a certain cure for all cases of leprosy has been discovered, but there is no doubt that the new remedy represents a very important advance in that direction.

FEW of the many claims for the discovery in America of human remains of high antiquity have withstood the test of rigorous examination on strictly scientific lines. Even when, as in a number of recent discoveries, a *prima facie* case appears to have been made out, the verdict still must be regarded as in suspense. Especial interest, therefore, attaches to an expedition of the Smithsonian Institution to Florida under the leadership of Dr. J. W. Gidley, of the National Museum, of which the object is to test the evidence for pleistocene man on sites in the neighbourhood of Vero and Melbourne on the east coast, where human skeletal remains have been found in association with pleistocene fauna. In the latest of three geological strata which have been examined by previous expeditions, there is clear evidence of disturbance in the presence of modern remains; but the question has to be decided whether the second stratum, in which human remains are associated with an undoubted pleistocene fauna, is to be regarded as undisturbed throughout or can be shown to be partly the result of a redeposit which has brought recent remains into association with the material of a pleistocene stratum.

THE lure of the treasure hunt is eternal. The latest venture, which is to be financed by a limited company formed recently, has as its object the discovery of a treasure hidden by Jesuits in Bolivia, when they were deported from the country by the Spanish authorities in 1778. For eleven years they had resisted the Government, and had been blockaded. During that time they had been unable to export any of the gold and silver derived from their mines or their precious stones. Two of these mines were known to be very rich, but they have never been located. It was agreed finally, that the Jesuits were to be allowed to depart, provided that they gave up this accumulation of treasure to the authorities. Rather than do this, they concealed it, and it has never been recovered, although a number of expeditions have looked for it. One of the Jesuits, Father Gregorio San Román, left with his brother, the Prefect of Callao, a description of the hiding place. This was handed down in the family until the beginning of the present century, when it came into the hands of Mr. Cecil Prodgers, who in 1920 passed it to Mr. Edgar Sandars, the organiser of the expedition which will proceed to Bolivia in the present year. Mr. Sandars believes that in excavations carried out in 1925 and 1926, he has discovered one of the entrances to the treasure chamber which the Jesuits constructed with the help of 500 Indians, some, and perhaps all, of whom they killed. He has, at any rate, found in a shaft which he partially cleared, a silver crucifix and a parchment warning intruders to withdraw from a spot dedicated to God Almighty in which 'a dolorous death' awaits him who dares to enter. Father San Román's document also suggested caution, as "enough poison to kill a regiment of the king has been laid about." The value of the treasure in present currency is estimated as £12,000,000.

MR. WOOLLEY's report on the excavations at Ur in the *Times* of Feb. 22, while adding further discoveries of human victims sacrificed in the royal tombs to those mentioned in his special interim report, records the discovery of the body of Queen Shub-ad, with the jewels which once covered her garments, and jewelled head-dresses, and suggests how and when the tomb of the king was rifled. As further discoveries are made, the more remarkable this revelation of the funerary customs of Ur and the beliefs they connote appears to be. One of the most important recent discoveries, though by no means so spectacular as some, is the form of the tomb itself. In the stone wall there was a doorway crowned by a true arch of brick, the tomb chamber was vaulted with arches, and the end was brought round to apsidal form and roofed with a half dome which was a cross between corbel work and a true dome building. A crudely fashioned arch had been found roofing a drain at Nippur belonging to the third millennium B.C. The present discovery makes it clear that the arch, corbel work, and the dome were familiar to Sumerian builders so early as the fourth millennium B.C.—a discovery of the greatest importance in the history of architecture.

THE original Wright biplane of 1903, the first power-driven man-carrying aeroplane to make a free and sustained flight, has been received at the Science Museum, South Kensington, on loan from Mr. Orville Wright, and will shortly be exhibited for the first time in Europe. Mr. Orville Wright and his brother, the late Mr. Wilbur Wright, began the study of aeronautics in 1896 subsequent to the death of Otto Lilienthal, whose gliding experiments had aroused their interest, and they made and conducted experiments with man-carrying gliders, utilising such knowledge as was then available. In 1901 they turned their attention to the application of power, and their research led to the production of this, the first successful aeroplane. The first flight was made by Orville Wright on the morning of Dec. 17, 1903, at Kitty Hawk, North Carolina, in the presence of several witnesses; and it lasted twelve seconds. It was followed by three other flights, the last being one of 59 seconds, when the distance covered was 852 feet; the machine was then overturned by a gust of wind while left unattended, and the damage resulting prevented further experiments at that time. Since the first flights were made, the aeroplane has been preserved in the Wright laboratory, and certain parts which were damaged beyond repair have been replaced by Mr. Wright himself.

Flying in an Avro-Avian biplane with a 30-80 h.p. Cirrus engine, Mr. B. Hinkler reached Darwin, in northern Australia, on Feb. 22, sixteen days after leaving Croydon. This compares with the 28 days taken by Sir Keith Smith and Sir Ross Smith on the first flight to Australia in 1919. The *Times* gives the total distance flown as 10,400 miles, measured from point to point of the flight, but points out that the actual distance flown was probably more than 12,000 miles. Mr. Hinkler covered the distance in fifteen stages, of which the last was the longest, involving 950 miles from Bima, in the Dutch East Indies, to Darwin. Another long flight was the 870 miles from Croydon to Rome, which occupied nearly thirteen hours. No second person was carried, and the passenger space was used for an extra petrol tank. A collapsible rubber raft was carried but was not required. There was no engine trouble at any point of the flight, and the only forced landing was in northern Africa and due to darkness. The weather was favourable throughout, but the flight was nevertheless a remarkable one, and brings nearer the day when the projected air-mail route to Australia will be accomplished. Mr. Hinkler has since continued his flight to Bundaberg, Queensland.

Sir Samuel Hoare, Secretary for Air, replying to a question in the House of Commons on Feb. 27 relating to Mr. Hinkler's flight, summarised excellently the main facts of the achievement. He said that the flight established several 'records.' "Mr. Hinkler achieved the fastest flight to date between England and Australia, shortening the time taken by Sir Ross Smith in 1919 by between 12 and 13 days; the longest solo and the longest light aeroplane flights yet made; and the first non-stop flight to Rome; whilst all places beyond India were reached in a shorter time than has been achieved by any other form of transport. The total flying time was 134 hours, so that the flight would have taken five days 14 hours if it had been made continuously, flying by day and night. Taking the total time spent on the flight, including nights and halts in the daytime on the ground, the average speed per hour throughout was well over 30 miles; whilst taking the time spent in the air only, it works out at an average of about 89 miles per hour. Further, 12,000 miles were covered without any repairs, a striking testimony to the reliability of machine and engine. One of the most striking features of the flight is that the machine employed was a standard Avro 'Avian,' with a Cirrus engine, which has been in use since 1926, and the only alteration made prior to the flight was the incorporation of extra tankage. A machine of this type costs, complete, apart from the extra tanks, only some £730, and an approximate estimate of the cost of the flight in terms of the petrol and oil consumed—as I have already said, no repairs were carried out—is £50. These figures are a striking indication of the great potentialities of aircraft for improving communications in the vast stretches of the Empire in which other means of communication are as yet non-existent or relatively undeveloped."

The Air Ministry has sent us a copy of the log of the Royal Air Force flight from Felixstowe to Karachi last autumn. This was the first part of the flight which was afterwards continued to the Far East. The machines were four metal supermarine Southampton flying boats, under the command of Captain H. M. Cave-Brown-Cave. The flight left Felixstowe on Oct. 14 and took a course via Plymouth, Bordeaux, Marseilles, Naples, and Athens to Aboukir. From there the course continued via Alexandretta, Ramadi, Basra, Bushire, Henjam, and Gwadar to Karachi. Stops were made at these and other places, but the log contains no mention of any accident or forced landing. All went well on the journey. The total flying distance was 4834 miles, and the average flying time of each aircraft at 67 knots was a few minutes under 72 hours.

British chemists will this year be afforded a unique opportunity of intercourse, both professional and social, with their colleagues in the United States of America and in Canada. Arrangements for the annual general meeting of the Society of Chemical Industry, which is to be held in New York, and for participation with the American Institute of Chemical Engineers and the (British) Institution of Chemical Engineers in visits in the United States and Canada are already nearing completion. The provisional itinerary commences on Aug. 11 at Southampton, and embraces Quebec, Shawinigan Falls, Montreal and Ottawa, Kirtland Lake, Niagara Falls, Akron (Ohio), Pittsburgh, Washington, Edgewood Arsenal, Wilmington, and New York, Great Britain being reached about Sept. 17. A number of 'tourist third cabin' berths have been reserved, and special facilities are being accorded by the White Star Line to members making their arrangements through the Society. It is believed that the total expenses of the complete trip need not exceed £150. The Society has allocated from the Messel fund ten grants of £50 each to members of the Society who wish to participate in the round trip and travel 'tourist third cabin,' and members wishing to take advantage of this offer are asked to apply promptly to the secretary. Those desiring to participate in the visit are urged to make early application to Mr. J. P. Longstaff, the secretary of the Society of Chemical Industry, or to Prof. J. W. Hinchley, the honorary secretary of the Institution of Chemical Engineers. Recent events in the political arena have shown how much good may accrue from opportunities of personal contact; it is to be hoped that the facilities which these arrangements afford may be largely used by chemists and chemical industrialists in Great Britain in the promotion of her own legitimate interests and in attaining a closer understanding of and regard for her friends and competitors.

ELECTRICAL engineers are watching with keen interest the development in Great Britain of the interlinking schemes which form an integral part of the Electricity Act of 1926. These schemes will ultimately tie together the power stations of the country. A beginning has already been made in connexion with the 132 kilovolt lines of the Central Scotland area. By linking the power stations together a more steady load is attained, and so a reduction in the amount of spare plant is effected. In other countries interlinking is also being effected, and power can be interchanged over distances of hundreds of miles. From a purely economic view, the heavier the load the greater the advantage of using high pressure. It is possible that in a few years' time pressures of 380 kilovolts may be employed. Progress in the design of electrical apparatus has been very rapid, and there seems to be no limit either to the output or the voltage of machines. By suitable coverings corona losses can be suppressed and the dielectric losses at very high pressures, whilst appreciable, are far from prohibitive. Probably the smallest-sized link between two networks will consist of two three-phase lines with suitable transformers. For economical reasons these transformers must be very large, and so the difficulties of transportation by road and rail limit their size. In the *English Electric Journal* for January, the total power loss at full load for a 100,000 kilowatt transformer is given as 850 kilowatts. This is converted into heat in the transformer, so very special arrangements have to be made for keeping it cool. As a rule the transformers are immersed in oil, which is kept circulating through pipes passing through external water coolers. A considerable supply of water is necessary. The rise of temperature of the oil at full load is about 30° C., and for a 50,000 kilowatt transformer working at this load, 15,000 gallons of water per hour are required.

RAILWAY electrification in India is making steady progress. On Jan. 5 the electrified suburban lines of the Bombay, Baroda, and Central India Railway, from Colaba in the south to Borivli in the north, a distance of 57 miles of track, was opened. Two lines of rails are electrified for the whole distance, and four for part of the distance. The power for the operation of the railway is purchased from the Tata Company's hydro-electric power stations, situated some fifty miles from Bombay on the Western Ghats. Power is transmitted to a receiving station at a pressure of 100,000 volts, and from thence is retransmitted to the substations situated along the line at 22,000 volts. At the substations the pressure is reduced and then converted into direct current at the working pressure of 1500 volts. The motor coaches are equipped with four motors each of 275 horse-power. The overhead high-tension wires are supported by lattice steel structures, which when necessary span eight tracks. The pantographs which collect the current from the overhead wires are operated by a vacuum pump, which also works the vacuum brakes. The sanding gear is of the gravity type and is controlled by electrically operated valves. In the event of mechanical failure, each mile of the equipment can be at once isolated. Each section also can be rapidly isolated by air break switches. Special care has been taken to prevent birds causing short circuits accidentally. All the cross-arms and beams are carefully insulated, so that it is practically impossible for the legs and the beak of the bird to be each in contact with separate conductors having a great difference of potential between them. In the overhead equipment alone, approximately 2000 tons of steel and 500 tons of copper were used.

A RECENT addition to the Department of Zoology of the British Museum (Natural History) is a mounted specimen of an immature Snow leopard from the north-west Himalayas; owing probably to the commercial value of the fur, museum specimens of this animal are rare. Mr. J. J. Joicey has presented to the Department of Entomology his complete series of Lymantriidæ, consisting of nearly 6000 specimens from all parts of the world. The Department has also received a valuable series of fleas from Manchurian ground squirrels; these fleas include species of practical importance, on account of the possibility that, like the tropical rat-flea, they may be concerned in the spread of plague. Recent acquisitions for the Department of Mineralogy include a series of fluorspars from the iron mines of west Cumberland, showing colourless, blue, and yellow cubes on the hæmatite ore. These are small, and as a rule quite inconspicuous, and very little is as yet known about them; but they must be taken into account in any theories dealing with the origin of the iron ores, and this of course has an important bearing on the finding of new ore-bodies. Various minerals, including willemite (zinc silicate), native silver, silver iodide, mimetite, scheelite, and copper ores from Northern Rhodesia, have been presented by Mr. R. Murray-Hughes. A sample of the meteoric dust ('red rain') that fell at Melbourne, Victoria, on Jan. 1, 1928, has been sent by Mr. E. J. Dunn. The trustees have authorised the purchase of a magnificent crystal of topaz from Madagascar. As an exhibition specimen this far surpasses any topaz previously in the collection, and it forms a companion crystal to the fine beryl purchased last year. It measures 12 cm. × 11 cm. × 10 cm., and weighs 2290 grams (11,450 carats, or just over 5 lb.). It is water-clear with a pale blue tinge and of gem quality.

The well-developed and brilliant crystal-faces are marked by complex and intricate pyramids and lines of growth, and the specimen is an instructive example of a crystal in which the process of growth has been abruptly arrested.

A NEW egg grading and marketing scheme has recently been brought out by the Poultry Advisory Committee, by which it is hoped to stabilise prices throughout the year. The National Poultry Council and two important associations of retail distributors in Great Britain have already assented to the principles of the scheme, and it is understood that the Government may provide time for the necessary legislation. At present there is no large, recognised market for English eggs, and transactions are made with comparatively small consignments, the organisation being insufficient for the development of the industry. Foreign eggs, however, are properly graded and packed, and it was only owing to the risk of their obtaining a better market on this account that an order as to the labelling of imported eggs was not recommended by the committee under the Merchandise Marks Act, 1926, until improvements in the grading and packing of British produce had been secured. The present scheme is to be voluntary, and available to all country and town packers provided they deal with a stated minimum quantity of eggs, registration under the scheme permitting the use of a 'national mark.' It is suggested that the Minister should be given power by act of parliament to define grades of eggs, the terms 'Specials,' 'Standards,' 'Mediums,' and 'Smalls' being recommended, and that only first quality eggs should be dealt with, sale being by weight. In addition, the scheme provides that all preserved British eggs should be marked as such, and imported eggs afterwards stored in Great Britain should also be appropriately labelled. It is hoped that all large egg producers will see the wisdom of coming under the scheme. It may well be the means of developing the egg industry in Great Britain.

DR. R. A. MILLIKAN, Director of the Norman Bridge Laboratory of Physics in the California Institute of Technology, Pasadena, has been awarded the Messel Medal of the Society of Chemical Industry.

AT the meeting of the London Mathematical Society at 5 P.M. on Thursday, Mar. 8, Prof. A. E. H. Love will deliver a lecture on "Biharmonic Analysis, especially in a Rectangle, and its Applications to the Theory of Elasticity." Members of other scientific societies are invited to attend.

THE Council of the Institution of Naval Architects has invited Admiral of the Fleet the Right Hon. Lord Wester Wemyss to succeed His Grace the Duke of Northumberland as President of the Institution. The election will take place at the opening of the annual general meeting at the Royal Society of Arts on Mar. 28 at 11 A.M. The Council of the Institution has awarded two premiums for the year 1927, one to Mr. H. J. R. Biles, for his paper on the "Effect of Wind Resistance on Superstructures and Ship Resistance," and the other to Mr. W. C. S. Wigley, for his paper on "Ship Wave Resistance—A Comparison of Mathematical Theory with Experimental Results—Part 2."

THE two Boyle Medals awarded by the Council of the Royal Dublin Society to Dr. W. R. G. Atkins (Pure Science) and to Prof. W. E. Adeney (Applied Science) were presented at a special scientific meeting of the Society on Feb. 15. The statements setting forth the grounds of these awards referred in Dr. Adeney's case to the valuable work he has accomplished during the last twenty years with respect to river pollution; this work has done much to elucidate the biological and chemical factors involved and had been generally recognised as of fundamental importance. In the case of Dr. Atkins, emphasis was laid on his work on the cryoscopic examination of physiological fluids; his researches on the osmotic pressures occurring in plants; his work on the relation of the *p*H value of the soil to plant distribution; on the photosynthetic changes in sea water; and on the significance of the phosphate content as a limiting factor in plant and animal production in the sea.

THE Carnegie Institute of Technology has issued a preliminary announcement of a second International Conference on Bituminous Coal, to be held at Pittsburgh on Nov. 19-24. The purpose of this Congress is again to present the results of recent studies of coal bearing on improved methods of utilisation and combustion. The programme will include the discussion of the fixation of nitrogen, the manufacture of substitutes for gasoline from coal, complete gasification of coal, high temperature distillation, low temperature distillation, coal-tar products, power, smokeless fuel, etc. An invitation is extended to scientific workers of all countries to take part in this conference. The president of the Carnegie Institute of Technology, Thomas S. Baker, will visit Europe during March and April to confer with fuel technologists who may consider the possibility of presenting papers or taking part in the congress in any other way. President Baker's address will be c/o Guaranty Trust Company, 1 rue des Italiens, Paris, where he will be glad to receive correspondence in regard to the meeting.

WE have received the annual report of the Society for the Provision of Birth Control Clinics for 1926–27. Two new clinics at Oxford and at Birmingham have been opened, making a total of nine clinics in operation in Great Britain. An increasing number of poor women is attending, and it is believed that much valuable assistance is rendered. The Society is entirely dependent upon private donations.

THE annual report of the South African Institute for Medical Research for 1926 has been issued. Sir Spencer Lister is now Director in succession to Dr. Watkins-Pitchford, who has resigned on account of ill-health. A summary of the work of the Institute is given; much of it has been devoted to plague research. A mosquito survey of the Union and a tuberculosis survey of the Native Territories are being undertaken.

The secretary of the Royal Horticultural Society reminds us that "Index Londinensis" has been prepared under the auspices of that Society. This was not mentioned in our note in the issue of Feb. 25, p. 296, referring to the publication. Messrs. Dulau and Co., Ltd., are now accepting subscriptions for the work.

Applications are invited for the following appointments, on or before the dates mentioned :—A chemist for research work for the improvement of mine rescue breathing apparatus, a physiologist to assist in investigations regarding mine rescue breathing apparatus and methods of resuscitation, and an investigator for research work on mechanical appliances for use in mines, each under the Safety in Mines Research Board —The Under-Secretary for Mines, Establishment Branch, Mines Department, Dean Stanley Street, S.W.1 (Mar. 10). An assistant to the lecturer in systematic forest botany, and a herbarium assistant, at the Imperial Forestry Institute, University of Oxford—The Secretary, Imperial Forestry Institute, Oxford (Mar. 12). A research student for work on bulb-growing problems at the Royal Horticultural Society's Experimental Gardens — The Director, R.H.S. Gardens, Wisley, Ripley, Surrey (Mar. 13). A bio-chemist at the Forest Research Institute, Dehra Dun, India—The Secretary to the High Commissioner for India, General Department, 42 Grosvenor Gardens, S.W.1 (Mar. 15). A reader in geography and education at Raffles College, Singapore—C.A. [T.], the Secretary, Board of Education, Whitehall, S.W.1 ; Scottish candidates, [T.], the Secretary, Scottish Education Department, Whitehall, S.W.1 (Mar. 17). Junior assistants at the National Physical Laboratory—The Director, National Physical Laboratory, Teddington (Mar. 17). A full-time lecturer in chemistry at the Chelsea Polytechnic—The Secretary, Chelsea Polytechnic, Manresa Road, S.W.3 (Mar. 24). A lecturer in geography in the Durham Colleges, University of Durham—The Secretary to the Council of the Durham Colleges, 38 North Bailey, Durham (Mar. 31). A lecturer or an assistant lecturer in zoology in the University of Bristol—The Registrar, The University, Bristol (April 14). A principal of Chelsea Polytechnic—The Secretary, Chelsea Polytechnic, Manresa Road, S.W.3 (April 30). A handicraft teacher for woodwork and light metal work under the Leicestershire County Council Education Committee—The Director of Education, County Education Offices, Grey Friars, Leicester.

Our Astronomical Column.

New Comet.—The first comet of 1928 was discovered photographically by Herr K. Reinmuth, assistant at Königstuhl Observatory, Heidelberg. Herr Reinmuth is well known as a discoverer of minor planets, having found more than a hundred of them, but this is his first comet ; as the new comet is near the ecliptic, it was doubtless found in the course of the routine search for minor planets. Its magnitude is 12½. The following positions have been obtained at Konigstuhl and circulated by the I.A.U. Bureau, Copenhagen :

U.T.	R A (1928.0).	N.Decl.(1928 0).
Feb. 22. 96160	$9^h\ 15^m\ 4^s$	21° 44′ 0″
,, 23. 96368	9 14 54·93	21 52 39
,, 24. 95736	9 14 42·20	22 0 6
,, 25. 93181	9 14 33·93	22 6 57

The motion is getting slower ; an estimated prediction for Mar. 4.0 is $9^h\ 15^m\ 36^s$, N. Decl. 22° 43′ ; the full moon will, however, prevent observation for a few days. There has not been time as yet to compute an orbit ; in any case, the above arc is too short to determine reliable elements. The slow motion probably implies that the object is at a considerable distance.

There is occasionally a double solution to the problem of finding an orbit from three observations ; an interesting case of this arose last year in the orbit of Gale's comet ; the observations of the first six weeks could be satisfied with periods of either 11 or 13 years, the former being found to be correct when a longer series of observations was available. Prof. T. Banachiewicz discusses this question in *Acta Astronomica* for Feb. 7, and gives the discriminating rules in a simple form ; the case to which he applies them (Orkisz's comet) has only a single solution ; an example with a double solution would have been more instructive.

A Large Sunspot.—A large sunspot, nearest the centre of the sun's disc on Feb. 21, was seen in London by many people through the screen of mist or fog prevailing about that time. A small telescope showed that the group consisted of a principal spot accompanied by an aggregation of irregular spots or penumbral markings to the south. The latter decreased considerably as the group crossed the disc. No unusual disturbance of the earth's magnetic elements has been reported. In Nature of Feb. 11, p. 220, a short account was given of a large prominence which was observed near a spot when at the sun's west limb. The recent group is either a return or a revival in the place of this earlier spot. Other particulars of the later and larger spot are given below, and it may be added that this is the first one this year to be recorded generally as a naked-eye object, although several other large spots are mentioned in Nature of Feb. 11.

The Gregorian Calendar in Egypt.—The 'Old Style' or Julian Calendar has now become practically obsolete, having taken nearly three and a half centuries to do so. The Orthodox Church in Greece adopted some years ago a modified form of the Gregorian Calendar ; instead of the 400-year cycle of the Gregorian calendar, it uses a 900-year one ; but as the two calendars are exactly the same for about seven centuries from the present time, the difference is not of immediate importance. The *Times* of Feb. 15 announces that the Synod of the Patriarchate of Alexandria, representing the Orthodox Church in Egypt, has decided to adopt the Gregorian calendar from Oct. 1, 1928 (Sept. 18, Old Style). Presumably it is following the same form of it as the Greek Orthodox Church ; the latter body also differs from western usage in the manner of computing Easter, which is made to depend on the actual moon, instead of using the simplified 'ecclesiastical moon.' The day used is that of the meridian of Jerusalem, thus getting rid of difficulties of longitude.

Research Items.

THE EVOLUTION OF MAN AND APES.—In volume I. of the new journal *Palæobiologica*, edited by Prof. Othenio Abel and published in Vienna and Leipzig (Emil Haim and Co.), there appears a paper by Prof. H. F. Osborn entitled "Recent Discoveries relating to the Origin and Antiquity of Man." This paper is less a review of recent discovery than a statement of Prof. Osborn's own opinion on the course that the evolution of man has taken. This differs from that usually held by the majority of investigators, in that it denies any close connexion between ape and man and places the ancestor common to the two stocks back to a period so remote as the Oligocene. While admitting that there are some anatomical resemblances, Prof. Osborn lays more stress on the difference in 'behaviourism' between man and the ape, and thinks that "scientific mythology has accumulated around the anthropoid apes, falsifying and exaggerating their human resemblances, minimising and ignoring their profound differences from man in habit and gait and in the anatomy and functions of the brain. . . ." Some resemblances, moreover, are to be attributed to convergence. There are two diagrams, both dated 1927, which express graphically Prof. Osborn's views on primate evolution. Propliopithecus at the base of the Oligocene is the common meeting ground of the two stocks. Dryopithecus and Pliopithecus are Miocene representatives of the Simian division, but with the exception of Hesperopithecus, on whose primate nature very great doubt has been cast (*v.* NATURE, Jan. 28, p. 148), there is no human representative actually known until towards the top of the Pliocene. This emphasises how much palæontological exploration has yet to do before there is enough evidence to form a clear opinion on this great problem of our own ancestry.

CARNIVOROUS HABIT OF AMERICAN MAGPIES.—In view of the well-known change of feeding habit in the New Zealand kea, a parrot of vegetarian tastes, which has developed a liking for the kidneys of living sheep, and has caused very serious damage to flocks in certain areas of the South Island, the description by E. R. Kalmbach of a similar development in the American magpie is of great interest (*U.S. Dept. Agr. Tech. Bull.*, No. 24, Oct. 1927). During the past ten years the magpie has begun to attack live stock on the western ranches, and since the first reports came to hand in 1917, its depredations have extended from Utah to Colorado, Wyoming, and Montana. Sheep, cattle, and horses have been attacked so severely that many have succumbed: recent reports mention that in one area several hundreds of cattle are destroyed each winter, and in another the magpie has become one of the greatest problems with which the ranchers have to deal. The magpies generally attack the animals about the loins, sometimes penetrating to the body cavity, sometimes reaching and devouring the kidneys. The origin of this habit in the States may throw some light on the predisposing causes which gave rise to the kea's depredations in New Zealand. It has been found that sheep were first attacked when they showed fresh wounds caused during shearing, cattle on fresh brand marks, and horses on unhealed saddle-sores. But the habit having been formed, the magpies learned to begin an attack without any direct incentive such as exposed raw flesh. The magpie concerned is the black-billed magpie (*Pica pica hudsonia*), a geographical race of the British magpie, and in normal circumstances the feeding habits of the two are similar.

DIURNAL VARIATION OF OXYGEN IN RIVER WATE —The degree of saturation of river water with oxyge is an important criterion in forming a judgment a to the suitability of a river for maintaining fish life This property is one frequently determined in wor dealing with the pollution of rivers, as the proportio of dissolved oxygen falls in the presence of oxidisabl organic matter. It has recently been found, howeve (Butcher, Pentelow, and Woodley, *Biochem. Jour.*, 21 945, and 1423-1435; 1927), that there are both diurna and seasonable variations in the proportions of dissolved oxygen and ammoniacal nitrogen in rive waters. This has been established by making hourly determinations over periods of 24 hours both o a contaminated stream in Suffolk and on a pur and unpolluted Hampshire trout stream. The diurna variations in the oxygen dissolved were greater in the case of the River Lark in Suffolk, although quite distinct in the pure River Itchen. The ammoniaca nitrogen, which varies in a sense opposite to that o the dissolved oxygen, also showed a diurnal variatio in the Lark, but was constant in the Itchen. The variations, especially in dissolved oxygen, are very large, ranging in some cases from 60 per cent. o saturation shortly after midnight, to 150 per cent. shortly after midday. The rise is attributed to the photochemical evolution of oxygen from organisms, and the fall to the absorption of this oxygen by organic matter, and by processes of respiration. It has thus become clear that in conducting a field survey of a river, the value of a single determination of the dissolved oxygen is of little value. Investigations over a period of 24 hours are necessary, and consideration must be given to such factors as time of year, actinic conditions, nature of plant and animal life present, as well as to the character of the river bed and its history with regard to past pollution. It is probable also that the diurnal variation in the supply of oxygen available for the needs of fish may have a bearing on their movements, a subject of constant interest to the fisher.

THE WHEAT BULB FLY.—The late Prof. J. F. Gemmill's observations on the life-history and bionomics of this fly, *Leptohylemyia coarctata*, have recently been published in *Proc. R. Phys. Soc. Edin.*, vol. 21, part 3, 1927. The fertilised eggs are laid during July, August, and early September in bare, loose soil, preferably among early potatoes and scarcely ever among cereals or in pasture. The egg develops slowly and the larva does not hatch until towards the end of January or in February. The newly hatched larvæ seek out, and by means of their mouth hooks bore into, young wheat plants, entering just above the so-called bulb. Reaching the centre of the plant they ascend for one to three inches, and the infected wheat plant soon shows withering of the central blade, and in early or poorly growing wheat the whole plant withers and dies. The larva makes its way to a second plant, which it affects in the same way, and it may destroy a third or even a fourth plant. If, however, the wheat plant is so far advanced when attacked as to show good lateral buds, the larva completes its growth in one of these and the plant saves itself by sending out additional lateral buds. The larvæ, which undergo two or three moults, are fully grown by the beginning of May; they then leave the plant and pupate in the soil half an inch or more below the surface. The flies emerge in late June and early July and, after having laid eggs, die off by the end of September.

The larvæ can infect barley, rye, and couch grass, and in these can complete their life-history. Couch grass appears to be the natural wild host in the area investigated. Prof. Gemmill recommended that in an infected area wheat should not be sown after potatoes or other root crop or fallow, and stated that if this were done in a single year he believed the numbers of the fly would be so reduced that it would not be a menace for many years to come. Short of this drastic action, he recommended to avoid sowing wheat after early potatoes, or to sow it after the middle of February, to arrange that potato fields shall not adjoin wheat fields in any one year, to get rid of couch grass, and to avoid deep burial of the wheat seed, for shallow-rooted plants form lateral shoots earlier. A field may be regarded as being badly infected in which during November the soil contains half a million to one million eggs of the fly per acre.

Textile Properties of Indian Cottons.—Progress in research work on the textile properties of standard Indian cottons is reported by A. J. Turner in *Bulletin 11*, issued by the Technological Laboratory of the Indian Central Cotton Committee. The foundation of the work lies in the annual testing of the fibre characteristics and spinning properties of some eighteen pure strains, the objects being generally, to accumulate data for the investigation of the methods of determining the intrinsic value of a cotton, and specifically: (1) to prepare a series of standards by which to judge other cottons, particularly new cottons produced by cotton breeders; (2) to determine the extent to which these standard cottons are affected by seasonal variations; (3) to determine the minimum weight on which a spinning test can be carried out satisfactorily; and (4) to assist in the marketing of these cottons by providing the cotton trade with detailed information concerning them. These objects have been achieved by submitting, year by year, typical samples of each variety to spinning tests which, though carried out on full-size machines, require only small quantities of material. The significance of small-scale tests has been investigated in accordance with object (3) above, and it has been shown that trustworthy results can be obtained by spinning duplicate lots weighing 5 lb. each. In addition, efforts have been made to determine the relationship between the physical properties of the fibres with spinning value, and while no conclusions of a positive character have been arrived at, the way seems to have been cleared for a more definite attack. Among the supplementary problems that have arisen in the course of work are those of the effect of temperature and humidity on cotton spinning, and the effect of subjecting cotton to repeated blow-room treatment. These are the subjects of *Bulletin 9* and *Bulletin 10* respectively. The latter has perhaps more of a technical than a general scientific appeal, but the former is interesting inasmuch as it embraces a very lucid résumé and criticism of previous work on the subject, and shows that Lancashire is by no means unique in the suitability of its climate for the manufacture of cotton goods.

The Anthraxolite of Sudbury.—The so-called 'coal' occurring in the pre-Cambrian rocks of Chelmsford, near Sudbury, has given rise to the suggestion "that terrestrial floras had a long pre-Devonian history." In the *Amer. Jour. Sci.*, Jan. 1928, Prof. A. P. Coleman shows conclusively that there is no need to assume pre-Cambrian land plants to account for the deposits in question. He finds that the veins of supposed coal cut across the stratification of a black slate, and reaches the conclusion that the slate was originally an oil-shale, and that the coal-like material must have reached its present position while it was plastic and still retained its original volatile hydrocarbons. The latter were probably driven off by the heat of the nickel-bearing eruptive of the Sudbury basin, residual carbon being left behind. Since the material differs both in origin and properties from *anthracite*, it is important that this name, with its inevitable implications, should not be applied. The term *anthraxolite*, used for coal-like deposits forming the end-products of the metamorphism of petroleum, is clearly more fitting. There remains the problem of the formation of oil-shales in the pre-Cambrian. At least one can conclude that the waters of the time were thronged with lowly types of plants and animals.

Apparatus for the Investigation of Fluorescence.—A new and simplified apparatus designed for the investigation of fluorescence is described in the *Chemiker Zeitung* of Jan. 11, by Dr. F. W. Müller, of Essen, from whom it may be obtained. Instead of the quartz mercury lamp, the source of ultra-violet light is a carbon arc lamp fitted with carbons containing iron and tungsten, which provide an almost completely continuous spectrum. The apparatus can be used even in daylight, and the ultra-violet light, filtered from visible rays, may be directed either from above or in a horizontal direction. A suitable resistance is provided with the apparatus, which can be used for direct or alternating current.

A Micro-Method for the Determination of Surface Tension and Density.—A method for the determination of surface tension and density, using only one piece of apparatus and a very small sample of liquid, down to 0·1 c.c., is described by V. R. Damerell in the *Journal of the American Chemical Society* for December. This apparatus is very simple in design and operation and may readily be constructed from the materials available in any laboratory. The results obtained were satisfactory for all except the most volatile liquids, such as ether, and the method has an accuracy of between 1 part in 100 and 1 part in 300.

The Interaction between Radiation and Electrons.—The main problems presented by the absorption and scattering of X-rays are discussed by Prof. A. H. Compton in the January number of the *Physical Review*. In his opinion the two phenomena are essentially similar, in that the whole momentum lost by the radiation is transferred to the electron, indicating that the action is sensibly instantaneous, but they differ in the extent to which they conform to classical electron theory. Experiment shows that the direction of emission of photoelectrons is given, at least statistically, by the Lorentz equations, whereas the preferred direction of motion of recoil electrons is perpendicular to the electric vector of the incident rays. Prof. Compton points out that conservation of angular momentum has also to be taken into account when dealing with circularly polarised waves. The point of view which he has adopted throughout is that of the older quantum theory, only one reference being made to the wave mechanics, in connexion with Wentzel's analysis of the angular distribution of photoelectrons.

An Improved Apparatus for the Removal of Dissolved Gases from Water.—The various forms of apparatus used for removing dissolved gases from water depend upon the use of heat and a vacuum, either separately or both at once. Those employing both heat and a vacuum are the most efficient, and a new apparatus of this type is described by Lorch, Williams, and Thompson in the *Journal of the American*

Chemical Society for December 1927. This apparatus is of simple construction and is adaptable to any amount of liquid or gas.

The Estimation of Gold and Silver in Sea Waters.—It is well known that sea water contains traces of gold and silver, and a new method for their estimation is described by M. Yasuda in the *Bulletin of the Chemical Society of Japan*, vol. 2, No. 12. Mercuric chloride is added to the sea water and then reduced to a fine suspension of metallic mercury, which removes the gold and silver (with the exception of that present in organic colloids) as it settles down. The amalgam thus obtained is absorbed in a bead of pure lead and, finally, the gold is obtained free by dissolving the other metals in nitric acid.

Colouring Matters of Carajura.—Carajura (or crajura or chica red) is a rare colouring material prepared from certain leaves and bark and used by various American Indian tribes. The main colouring matter is a crystallisable substance known as *carajurin*, and an interesting investigation of its constitution by E. Chapman, A. G. Perkin, and R. Robinson is described in the issue for December last of the *Journal of the Chemical Society*. Perkin (1914) considered carajurin to have the empirical formula $C_{18}H_{16}O_5$, but it is now shown to be $C_{17}H_{14}O_5$. Carajurin on demethylation yields salts of *carajuretin*, and these have been shown to be identical with certain flavylium salts prepared synthetically, thus enabling a provisional formula to be advanced for the constitution of carajurin. The synthesis of this substance is now being attempted and a second colouring matter, *carajurone*, has been isolated from carajura. The investigation involved a large amount of experimental work, including the synthesis of a number of new compounds.

Yield-point in Iron at Various Temperatures.—The *Journal of the Royal Technical College, Glasgow*, for December 1927 contains several papers of considerable importance, not the least interesting of which is one on the yield-point in iron by Prof. J. Muir. The work was carried out on some hard-drawn wrought-iron wire, 0·024 in. in diameter and of composition: carbon, 0·05 per cent.; manganese, 0·30 per cent.; phosphorus, 0·016 per cent.; sulphur, 0·032 per cent. Before use the material was annealed in nitrogen at a temperature of approximately 800° C. The stress at the yield-point, the extension taking place there, and the time required for that extension were all measured at temperatures ranging from 17° C. to 250° C. Excluding two results at 185° C. and 215° C., which were doubtful, the amount of the extension at the yield-point shows a progressive drop from 4·65 per cent. at 17° C. until at the highest temperature used (250° C.) the yield-point so characteristic of iron at ordinary temperatures has practically disappeared (0·5 per cent.), a stress-strain curve similar to that, for example, of a non-ferrous metal being obtained. Another interesting observation was concerned with the rapidity with which these extensions took place. At 17° C., 150 minutes were required for the extension to complete itself. At 52° C. the extension took place very much more rapidly and was complete in about 8 minutes. At 210° C. and 215° C. the yielding took place with startling rapidity in about a second, and was characterised by a number of very rapid jerks, a phenomenon which had entirely disappeared at 250° C. The loads at which the yield-point occurred varied from 19·4 lb. at 17° C. to 20·25 lb. at 195° C. to 14 lb. at 250° C. A load of 1 lb. corresponded very nearly to a stress of 1 ton per square inch.

Domestic Applications of Electricity.—Two papers were read on the domestic applications of electricity on Feb. 16 to the Institution of Electrical Engineers. The load on the various power stations has been rapidly increasing in Great Britain for a number of years owing to the extensive use of labour-saving appliances. The importance of standardising the systems of wiring in use and of making provision during the building of houses for the installing of the electric wires was emphasised. An experiment carried out recently at Birmingham showed that the saving in the cost of building an 'all electric' as compared with an ordinary house is about fifteen per cent. In the Weir system of houses for working classes the cost of wiring is reduced to a minimum. The parts of the houses are all duly wired in the factory, so that when the house is erected by ordinary workmen, an electrician can make all the requisite connexions in about two hours. The total cost comes to about £5 per house. Electric cooking is successful commercially, there being very few dissatisfied consumers. The standard rate of consumption for cooking is one unit per day per person. The radiant system of cooking is becoming popular. In this system the oven elements consist of two vertical radiators which radiate heat directly on to the food. As the food is grilled on both sides simultaneously, much time is saved, and it is claimed that the quality and flavour are greatly improved. The time required to cook a 5 lb. joint of beef is 40 minutes and the energy consumption is only half a unit. An ordinary electric oven takes more than twice as long and takes four times as much energy.

Stresses on High Tension Cables.—A progress report by the Research Department of the Detroit Edison Company, which was presented at a meeting of the Association of Edison Illuminating Companies, held at Colorado Springs on Sept. 26, gives a very interesting study of the mechanism of the actions which cause the failure of high tension electric cables. In experiments with a new three-core lead-covered cable of modern type, it was found that internal pressures as high as 85 lb. per square inch were sometimes developed after the current had been flowing for several hours. If the current is kept flowing for many hours the pressure begins gradually to diminish, due largely to the stretching of the lead. When the current is now diminished to half its value, vacuous spaces develop in isolated regions along its length; the pressure falling to about 15 inches of mercury below atmospheric pressure. The vacuum in these spaces may exist for days if the cable is left unloaded. These vacuous spaces are subjected to a high electric stress, and cumulative ionisation ensues, an electric discharge taking place through them. The shape of these spaces being unknown, it is impossible to compute the electric stresses to which the insulating material is subjected. The experimental results prove the novel result that the cable insulation produces a definite rectifying action on the current flowing through it. The direct current component of the voltage thus produced was found to be of the order of eight per cent. of the peak value of the alternating current voltage. It is stated that this is detrimental to the cable and that the relative magnitude of this effect increases with the length of time the cable has been in use. Resin oil evolves large quantities of gas under electrical bombardment. From this point of view its use is deleterious. On the other hand, its conductivity improves with temperature, and this generally has the beneficial effect of relieving the electric stress on the air cavities.

The Seventh Congress of the Far Eastern Association of Tropical Medicine.

THE seventh Congress of the Far Eastern Association of Tropical Medicine was held in Calcutta on Dec. 5–24 last. The Association was founded at Manila in 1908, where the first congress was held in 1910. Since that date congresses have been held at intervals, usually of two years (except during and for a short interval after the War), at Hongkong, Saigon, Weltevreden, Singapore, and Tokyo. The Calcutta Congress was the largest that has so far been held, and was attended by about 900 members. The headquarters were in the School of Tropical Medicine and the adjacent Medical College.

The scientific business of the Congress was conducted in six sections: (i) Clinical medicine and surgery, ophthalmology, dermatology, etc. (apparently all that is not specifically included in the titles of the other sections); (ii) State medicine and hygiene, child welfare; (iii) plague, cholera, dysentery, sprue, intestinal infections, bacteriophage, leprosy, tuberculosis, and bacteriology; (iv) malaria, kala-azar, protozoology, typhus-like diseases, leptospiræ, medical entomology, and helminthology; (v) nutrition, deficiency and endocrine diseases, immunology, chemicotherapeutics, rabies, and pharmacology; (vi) veterinary. Several of these were divided into subsections.

A total of 228 papers was read; abstracts of these were published beforehand [1] and were available for all members. Judging from these abstracts, the meetings of the sections must have been packed with interest. It is impossible to mention even a tithe of the titles that attract attention on turning over the pages of the handbook; and the following notes on a few of the papers are really only in the nature of a random sampling.

Dr. Gian Singh considered the incidence of pulmonary tuberculosis in Multan City, according to sex, religion, age, occupation, and residence in different parts of the city. His study leads him to recommend that Government should oblige municipalities to take housing schemes in hand, to open up congested areas, and to enforce building by-laws prohibiting high houses in narrow lanes; that municipalities should employ health visitors to carry on propaganda among the women against certain customs observed by them in the puerperal period; that the people themselves should form anti-purdah and anti-child marriage societies, and that the working and economic conditions of low-paid Government servants should be improved by Government.

Lieut.-Colonel Russell, considering population and public health in India, finds that the population is outrunning the means of subsistence, hence unemployment, rising prices, and reductions in the standard of living of agricultural and industrial workers. As to the possibility of these phenomena being countered by improved agricultural methods and the production of much larger quantities of food, the author considers it unlikely that the situation can be thus influenced to any extent in the long run. In the Madras Presidency the population is within a million of the upper asymptotic limit, and even now considerable quantities of rice are being imported from Burma and Ceylon.

Dr. d'Herelle has three papers on bacteriophage, a subject with which his name is especially connected, and which has attracted much interest in recent years. Bacteriophage is a 'principle' which effects the dissolution of bacteria, reproducing itself as it does so. According to d'Herelle, it is a filter-passing parasite (*Protobios bacteriophagus* d'Herelle 1918) of the bacteria. It is present in the intestine of every man and animal, and in normal individuals develops upon the saprophytic flora there present; by a process of adaptation (demonstrable *in vitro*), which is more or less rapid according to circumstances, it becomes able to parasitise any invading bacteria. The end result, recovery or death, in the bacterial intestinal diseases of man and animals, depends on the power of the bacteriophage to attack and destroy the pathogenic organisms. Bacteriophagy is thus the result of an infectious disease prevailing amongst bacteria. Bacteriophage treatment has been eminently successful in bacillary dysentery, and in cholera has been fully efficient in the great majority of cases.

Lieut.-Colonel Acton and Major Chopra, investigating the action of quinine on the malarial parasites, found that by increasing the degree of alkalinity in the intestines they obtained a greater diffusion of quinine into the circulating blood; hence the blood concentration of quinine was higher when alkalis were administered at the same time. Still, the concentration attained in the circulating blood is considered to be insufficient directly to kill the parasites; but sublethal concentrations are able to paralyse their movements to a certain extent, and the parasites fail to penetrate the envelope of the red blood corpuscle and so to reach their food. These sluggish parasites are swept off the corpuscles by the friction of the blood stream and die of starvation.

Lieut.-Colonel Christophers and Dr. I. M. Puri ("Why do Anopheles Larvæ feed at the Surface, and How?") show that the Anopheles larva is morphologically adapted to feed at the surface, and point out the advantages it obtains by doing so. (Most waters have a special bacterial and flagellate surface film; there is also a subsurface layer of organisms that aggregate below the surface film, either because they are lighter than water, or because they actively seek this position.) The feeding process is described.

Lieut.-Colonel S. P. James and Drs. Nicol and Shute consider the habits of Anopheles in relation to their rôle in the spread of malaria—an interesting paper, since the work was done in England, in connexion with the provision of supplies of infected mosquitoes for transmitting malaria to certain mental patients. The same authors have a paper on experiments on the treatment of malaria in England. Lieut.-Colonel James contributes some remarks on anti-malarial measures for poverty-stricken regions; no one doubts, he says, the efficacy of the established methods of malaria control, but they are difficult and expensive, and it is important to discover a method which can be applied in poorer countries, such as those of south-eastern Europe. In spite of the Commission appointed by the League of Nations Health Committee, such a method is not yet forthcoming; but the first aim should be to reduce the severity rather than the incidence, to combat the disease itself on its appearance in the human or insect hosts; the disease then soon ceases to be of importance. Besides doing this by direct methods, it is essential to improve the economic and social conditions of the people and their general well-being and standard of life; Dutch and Italian schemes for such purposes are already in existence.

Lieut.-Colonel Knowles considers the kala-azar transmission problem and the factor of resistance; he tells the interesting story of recent research into this problem, the arguments which led to the incrimination of the sandfly *Phlebotomus argentipes* as the transmitter, feeding experiments and their results, the working out of the history of the parasite in the fly (the whole life-cycle of the parasite is fully considered in a paper by Major Shortt), and refers to the parallel work of Patton and Hindle in China. The final link in the chain of proof, namely, transmission from man to a human volunteer by means of the sandfly, is still lacking, probably owing to the fact that man, instead of being very susceptible, is extremely resistant to infection by kala-azar.

Pp. iv+176. The Indian Empire: being a Brief Description of the Chief Features of India and its Medical and Sanitary Problems. Pp. vii+346+20 plates+4 maps. (Calcutta: Far Eastern Association of Tropical Medicine.)

There are numerous papers on helminthology and on medical entomology; but these notes must close with a mention of Mr. Senior-White's paper on progress towards the realisation of the biological control of mosquito breeding, in which, after recounting the older methods, the author considers the connexion between the hydrogen-ion concentration of the water and the species of mosquitoes that breed in it. Acidity other than that due to carbon dioxide is definitely inhibitory to anophelines; but only extremes of 'natural' pH have any such effect. The presence of very small amounts of ammonia, however, are destructive to larvæ; and the probability that bacteriophages (*v. sup.*) can be isolated by which the nitrifying bacteria can be destroyed, and hence the conversion of ammonia into nitrites and nitrates delayed, gives a hope that practical measures may be devised on these lines.

Perhaps it is scarcely necessary to add that all the activities of the Congress were not on these strenuous lines. The programme specifies such things as an evening reception by H.E. the Governor of Bengal at Government House, another by the Trustees of the Indian Museum at the Museum, a conversazione by the Asiatic Society of Bengal, a garden party at Government House, river trips and 'bus tours, visits to works, scientific cinema films, a play in an Indian theatre, as well as other diversions. The scientific meetings concluded on Dec. 11, after which three tours were arranged, one through northern India, one through southern India (these lasting a fortnight), and one through Bihar and Orissa (lasting a week). The "Souvenir—The Indian Empire," presented to all members, is "a brief description of the chief features of India and its medical and sanitary problems"; it fulfils a similar function to the Local Handbook of the meetings of the British Association. Among its 18 chapters are included a résumé of Indian history, and accounts of the history of European medicine in India, of indigenous systems of medicine, of Indian archæology, zoology, botany, geology, weather, and art. Its 340 pages are illustrated by 20 plates of photographic reproductions, several—including the frontispiece, a magnificent peak in the Sikkim Himalayas—of great beauty. Everything seems to have been done to make the Congress a success; and the members can scarcely fail to have enjoyed an intensely interesting as well as a very profitable visit to Calcutta.

J. STEPHENSON.

The Origin of the Japanese Earthquake of 1923.

DR. N. YAMASAKI, professor of geography in the Imperial University, Tokyo, contributed to the official report some valuable physiographic studies on the Japanese earthquake of 1923, which he has recently brought to the knowledge of western readers by translating them into English (*Jour. Fac. Sci.*, Imp. Univ., Tokyo, vol. 2, pp. 77-119; 1926). They are of great interest, chiefly on account of the light which they throw on the origin of this remarkable earthquake.

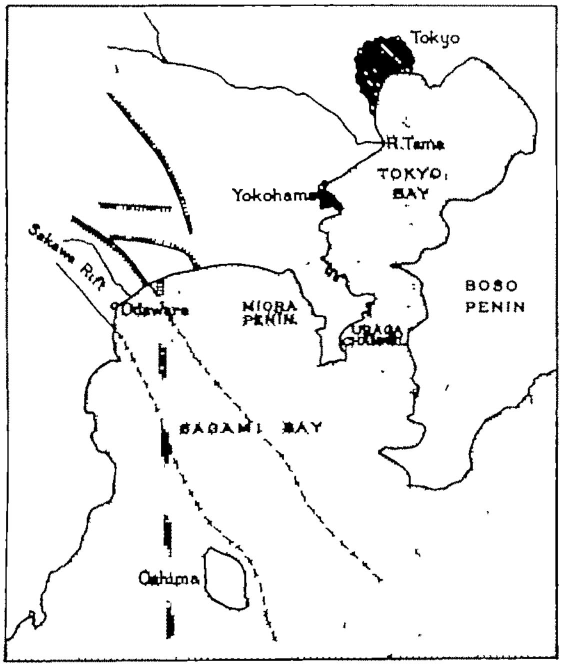

FIG. 1.

The principal features of Prof. Yamasaki's map are here reproduced (Fig. 1). The river Sakawa runs into the Bay of Sagami on its north-west side. The valley is part of a remarkable rift valley, bounded on the north-east side by a fault-scarp from 200 to 300 metres in height. It was formed by blocking movements of comparatively recent date. Earthquakes, indeed, still occur in the district, one of the latest being the strong Odawara earthquake of 1633. The earthquake of 1923 was very severe in this part. Many villages at the foot of the scarp were totally ruined and the level surface of the fields was thrown into gentle undulations. Still more remarkable than the rift valley on land is its continuation into Sagami Bay. A great trench runs along the axis of the bay in the direction S. 35° E. Near the bottom of the trench the slope is gentle, while the straight side walls are steep and high. The north-east wall is an extension of the fault-scarp on the same side of the Sakawa valley, while the south-west wall is also a steep scarp passing a short distance to the east of the volcanic island of Oshima.

Before the earthquake of 1923, the depth of the trench varied from 1500 to 2000 metres. On the north-east side of the trench, the submarine plateau consists of two steps, the lower one 12 km. wide at a depth of from 1000 to 700 metres, the upper one forming a shelf with a depth of less than 200 metres. One other feature deserves notice—a fiord-like furrow along the floor of the Uraga Channel, with a branch on the east continued into the Boso peninsula as the depressed tract around Tateyama.

The earthquake of 1923, in Prof. Yamasaki's opinion, may be considered as the direct effect of an enormous blocking movement in the district. The most remarkable displacement was of course that which occurred in Sagami Bay. The subsidence was greatest, from 100 to 210 metres, along the axis of the trench. The margin of the uplifted block on its north-east side was raised 250 metres, that on the south-west side 120 metres. Besides these tilted blocks in the deep sea, the shelf of land along the coast was also uplifted, though to a much less extent. The land was tilted as a whole with its raised margin to the south, the uplift gradually decreasing to the north as far as the Tama valley, after which elevation gave place to depression, never great in amount but covering a wide area. In consequence of these great movements, many fault-lines have newly appeared in the Boso and Miura peninsulas. Slips also occurred on the sea-bed where the slope is steep, those on both sides of the Uraga furrow being the most remarkable.

In this and other memoirs, attention is concentrated chiefly on the vertical displacements. The re-survey of the district has, however, revealed horizontal movements. These are described by Prof. A. Imamura in a brief paper read before the International Union of Geodesy and Geophysics at the Prague meeting in September last. Assuming that the positions of two points about fifty miles north of Tokyo have remained unmoved, it appears that the island of Oshima has shifted 3·78 metres in the direction N. 8° E., Manziro-dake on the west coast of Sagami Bay 2·86 metres N. 9° E., Sengen-yama on the north coast 2·75 metres N. 112° E., and Nokogiri-yama on the east coast 2·57 metres N. 145° E. Thus, generally speaking, the whole epicentral district has made a clockwise twist about a vertical axis somewhere in Sagami Bay.

C. D.

British Industries Fair.

THE distinguished general who called the English a "Nation of Shopkeepers" was aiming a scathing insult at our people. By the same token, Adam Smith and the older economists must have turned in their graves when the Government decided to take active steps for the encouragement of commerce. Times have changed. We now aspire to the proud title of a "Nation of Shopkeepers." In order to pay the appalling bill for the War and to restore our country to its pristine wealth, production and trade, especially export trade, must be stimulated by every resource, private or public. Faced by intensified foreign competition and the loss of our pre-eminence in the control of raw material, we are turning to scientific research, to a higher organisation of industry, and not least to a reasonable propaganda on the commercial side. A useful exhibition of our industrial effort is now organised annually by a Government department, the Department of Overseas Trade (Development and Intelligence).

This year's Fair, held in London and Birmingham on Feb. 20–Mar. 2, showed a marked increase in the number of exhibitors and the range of industry represented. By the admission of the general public during the daytime at a nominal charge, the cathedral-like silence of the earlier fairs has been replaced by a livelier atmosphere, without derogation of the serious purpose the organisers of the Fair have in view. Noticeable this year was the evidence of rapid exploitation of recent scientific discoveries. The British Drug Houses, Ltd., for example, already have on the market Vitamin D in the form of a sugared pill, equivalent to so many hours of sunshine. This firm has also prepared a form of malt containing three vitamins. Several forms of apparatus, some of them fitted with electric clocks, were on view for the administration of ultra-violet rays. Even powder puffs are now treated with these rays.

In the wireless section, many portable sets were shown, giving excellent results, in some instances at quite a moderate price. Lilley's sounding instrument warns a ship approaching rocks and records the depth of water under a ship's bottom. Even in the realm of toys, science has raised its standard. 'Thirsty' is the name of a toy dog the protruding tongue of which indicates changes of weather. The whole world will welcome the new instrument for testing the accuracy of singers' voices, exhibited by the Institute of Patentees.

Complexity is not necessarily a characteristic of modern invention. There is, for example, a simple pad called the 'Solapad,' worn next to the skin over the abdominal nerves, which claims to prevent travel sickness in its various forms—sea, train, motor-car, etc. The Ice Store Portable Refrigerator makes ice of the purest quality at an operating cost of one penny per day. Attention may again be directed to the 'Thermega' electro-radiant blanket, a simple and cheap but most useful electrical application. We have no difficulty in accepting the makers' assurance that dampness in beds is a source of great danger, lowering the vitality even when not a direct cause of disease. The blanket has also many obvious medical applications. Messrs. Grieve and Gordon are extending the use of eucalyptus oil as a disinfectant. Imperial Chemical Industries, Ltd., again provided an interesting exhibit, enlivened by a cinema show. Their nitrogen campaign for the improvement of grassland is making good progress. A new fertiliser, called 'Nitro-chalk,' has been placed on the market, consisting of a mixture of ammonium nitrate and dried carbonate of lime. Ammonium nitrate is unsuitable as a direct fertiliser, but can be made available as a fertiliser by mixing with carbonate of lime, of which the company has an ample supply at Billingham. The mixture has a nitrogen content of 10 per cent., and its price will be such that the farmer will only be paying for the nitrogen, the lime—itself a valuable fertiliser in certain soil conditions—being given to him free of charge.

Apart from the evidence provided by statistics of sales effected by the exhibitors, the visitor will be left in no doubt as to the usefulness of this Fair, and for those who are despondent about the future of British industry, it should serve as a tonic.

Spectra and Atoms.

"SPECTRA and Atoms" formed the subject of a lecture by Prof. A. Fowler before the Chemical Society on Feb. 23, when he gave in brief outline an account of the relations existing between series lines in the spectra of elements, and discussed how these relations harmonise with modern views concerning the electronic configuration of the atom.

Early investigations were primarily directed to the identification of regular series of lines which can be represented by simple formulæ, each line being described as the difference of two wave-numbers or terms. Recognition was early extended to different types of series—principal, diffuse, sharp, and fundamental—and Rydberg showed how the various series in the same spectrum are closely interrelated, leading to a simplification in the mode of representation. Prof. Fowler proceeded to discuss the application of Ritz's combination principle, and the restrictive effect therein of certain selection rules. In some spectra, all terms other than those of *S* type have two values, giving rise to series consisting of doublet lines, and in others three values yielding triplets, but a combination of two doublet terms does not give four lines, and one of two triplet terms yields only six of the nine lines arithmetically possible. For the application of the relevant selection principle, the components of each multiple term must be distinguished by so-called inner quantum numbers.

In 1913, Bohr's theory came to illuminate the subject of spectral structure by its interpretation of spectroscopic terms as energy levels of the atom; spectral lines are regarded as representing the energy lost by an atom when it passes from a stationary or non-radiating state of a certain energy to another of smaller energy, the possible states being governed by quantum considerations. In its normal unexcited state the atom is in the condition of lowest energy, but it may pass to states of greater energy by the absorption of radiation or by collisions of certain types.

Prof. Fowler continued his discourse with a discussion of electronic orbits. The energy representative of a particular orbit is dependent on its size and—on account of the varying velocity of the electron and the consequent relativity variation of its mass—slightly different for orbits of the same major axis but different eccentricities. This view led to an explanation of the 'fine structure' of the lines of the Balmer series of hydrogen. Of the two quantum numbers employed, one, the principal quantum number, determines the size of the orbit, and the other, the azimuthal quantum number, determines its shape.

Bohr's ideas regarding the probable distribution of the electrons in atoms have been extended remarkably in recent years, so that it has become possible to specify with certainty the electron arrangement for most of the elements and the most probable arrangement for the remainder. These developments were made possible by advances in the analysis of complex spectra, and particularly by the discovery by Catalan, at that time working in Prof. Fowler's laboratory, of higher multiplicities. Another great advance originated in an investigation by Russell and Saunders of the spectrum of calcium, when it was observed that some of the new triplet terms, which also violated the familiar selection rule, represented amounts of energy greater than were necessary to drive a single electron completely out of the atomic system, indicating that a second electron was displaced while the other still remained in the system. Hence spectroscopic terms now have to be defined by 'group quantum' numbers, representing a kind of resultant of the orbital numbers.

Prof. Fowler referred to the important contributions of Pauli, Heisenberg, and Hund, and to the significance of two other quantum numbers involving the orientation of the orbit and the orientation of the spin of the electron respectively, and then surveyed the spectra of some of the elements in relation to the new table of atomic structures. The general conclusion is that all the main features of the spectrum of an atom can now be theoretically predicted if the electron configurations are known, and vice versa. The spectra of ionised atoms are also of great importance; Prof. Fowler referred in this connexion to Paschen's work on aluminium, to his own work on magnesium and silicon, and to the results of Millikan and Bowen. When atoms resemble one another in everything but nuclear charge and mass they are said to be 'isoelectronic,' and the relations between their spectra are beautifully simple. The lecture terminated with a description of Bowen's recent investigations leading to recognition of the 'nebulium' lines—lines appearing in the spectra of nebulæ and hitherto attributed to an unknown element—as being due to singly ionised oxygen and nitrogen and doubly ionised oxygen.

University and Educational Intelligence.

EDINBURGH.—The chair of chemistry, which will become vacant at the end of the current academic year by the resignation of Sir James Walker, has been offered by the Curators to Prof. James Kendall, professor of chemistry and Dean of the Graduate School in the University of New York, who has intimated his acceptance. Prof. Kendall, after graduating in Edinburgh, engaged in research under Arrhenius in Stockholm. In 1913 he was appointed instructor in chemistry in Columbia University, New York, and in 1922 succeeded Prof. Alexander Smith in the chair of chemistry in Columbia University. He went as professor of chemistry to the University of New York in 1926.

LONDON.—Dr. W. E. Gibbs has been appointed as from April 24 to the Ramsay Memorial chair of chemical engineering tenable at University College. Dr. Gibbs was educated at the Liverpool Institute High School and the University of Liverpool. He has had considerable technical experience, and since 1918 he has been chief chemist to the Salt Union, Ltd., where he has been responsible for the formation and organisation of the Research Department and the design and construction of the research laboratories. His published work includes "Report on Disperse Systems in Gases" (Brit. Assoc., Fourth Colloid Report, 1922) and "Clouds and Smokes: The Properties of Disperse Systems in Gases and their Practical Applications" (Churchill, 1924).

OXFORD.—A new mathematical professorship has been founded in accordance with the provisions of a trust created by the late Mr. Walter Rouse Ball, senior Fellow of Trinity College, Cambridge, who expressed a hope (but without making it in any way a condition) that it might be found practicable for the professor to include in his lectures and treatment historical and philosophical aspects of the subject. The holder of the office will be known as the Rouse Ball professor of mathematics, and he will receive a stipend of £1200 a year from the endowment fund of £25,000. Mr. Applebey, in introducing the statute, stated that it is proposed to establish a professorship on mathematical physics which will be attached to Wadham College.

Mr. John Purdon Maxton, of the University of Glasgow, has been appointed a research officer in the Agricultural Economics Research Institute.

Dr. T. V. Barker, of Brasenose College, reader in crystallography, has been appointed secretary to the curators of the University Chest as from April 1 next.

In his annual report on the University Observatory, published in the *University Gazette* for Feb. 22, Prof. H. H. Turner reviews the work that remains to be done before the international astrographic survey of the whole sky is completed. For one reason or another, several of the countries which originally agreed to co-operate, have failed to carry out their intended programmes. The Oxford staff has been able to assist the Vatican Observatory with its section, and it is now proposed, if funds be forthcoming, to undertake the section to the north of the Oxford section, so as to cover that part of the sky which should have been surveyed by the Potsdam Observatory. The seismological investigations initiated by John Milne in 1913 are being continued, and studies of the mass of Venus have been reviewed by Dr. Fotheringham.

A vacancy in the office of Keeper of the Department of Antiquities in the Ashmolean Museum is advertised. The stipend has been fixed at £1000 per annum.

Calendar of Customs and Festivals.

March 2.

ST. NUNNE, or Nuanita, daughter of an Earl of Cornwall and mother of St. Patrick. Two wells were sacred to her, one at St. David's, one in Cornwall, at Alternon, the latter having miraculous powers of curing insanity.

March 4.

From Feb. 25 until Mar. 4 (O.S.) is a period of eight days and seven nights known in Algiers and Morocco by various names, such as *ld-hsûm* or *tamgart*, meaning 'the old woman,' presumably because the winter is coming to an end, or the 'Master of the Snow,' *Ḥalyqn*. This period, which is represented as a bitterly cold time of the year, is marked for its rain, wind, and snows, dangerous to people, animals, and crops. No one cares to travel, agricultural operations are suspended, and flocks and herds are kept under shelter so far as possible. A thunderstorm at this time is hurtful to little children, animals, and bees, and makes milk and honey scarce; but if an east wind blows, the year will turn out good without scarcity. It is believed that the world will come to an end during this period. Moreover, legends indicate that this is a period of 'borrowed days.'

Variants current in the East, and especially a Palestinian version, put the matter clearly. An old woman, while feeding her flocks, mocked February because he had sent no rain. Three days only of the month remained. February borrowed three days from March and sent rain for six days, which washed the old woman and her flocks into the sea. Therefore the first three days of March are known as *El Mustakridât*—the 'Lent out ones' (see Westermarck, "Ritual and Belief in Morocco," vol. 2, p. 174 *sqq*.). In England, March 'borrows' days from April.

March 5.

ST. PIRAN, PERRAN, or PHRAN.—One of the many Irish saints who are conspicuous in Cornish hagiology. Very little is known of his life and acts. He is said to have been born in Cork or Ossory about A.D. 352, and after passing the greater part of his life in Ireland, to have retired to Cornwall, where he lived near Padstow and died at the age of two hundred years. This remarkable span of life may be an attempt to eliminate chronological inconsistencies in the lives of the saint which appear to confuse him with St. Kieran, the precursor of St. Columba, who went to Scotland in the year A.D. 560.

St. Piran is an important figure in Cornish legend. His miracles in Ireland and his voyage to Cornwall on a millstone have already been mentioned (NATURE, Jan. 21, p. 121). At least three localities in the country are known by his name, Perran-aworthan (Perran on the noted river), Perran-uthno (Perran the lesser), and Perran-Zabulo (S. Perrani-in Sabulo—Perran in the Sands), where he lived. The Church of Perran is also associated with the cult of St. Agnes. St. Piran is the patron of the miners, and Mar. 5 is kept as a holiday in his honour. According to the legend, he discovered tin; a black stone which he used in building his hearth melted and produced a beautiful white metal. St. Chiwidden, to whom he communicated his discovery, devised a method of producing the metal in quantity. The saints imparted their knowledge to the Cornish people and the occasion was celebrated by great rejoicing so that 'as drunk as a Piraner' became proverbial. The fame of Cornish tin spread far and wide, eventually reaching Tyre and giving rise to the Phœnician trade. To protect the sources of tin from foreigners, the markets for this trade were confined to the islands, and the tribes of St. Piran and St. Agnes built the rounds and earthworks as a further protection. St. Piran is thus anachronistically associated with two phases of Cornish prehistory—the discovery and working of tin, and the construction of prehistoric forts and earthworks.

Although it is possible that this story may be merely a piece of folk mythology of comparatively modern origin, it is also possible that it preserves a tradition from an older dispensation. St. Chiwidden is an entirely mythical personage, but Chi-wadden means 'a white house,' *i.e.* the blowing or smelting house, and in the corrupt form of Jewwhidn or Jew's house is applied to the old blowing houses. St. Piran was patron of a holy well at Perranzabulo, which had the property of healing sick children, and here may certainly be regarded as the representative of an earlier local deity.

ST. CASIMIR OF POLAND.—Son of Casimir III., King of Poland, *b*. 1458, *d*. 1483, led a life of abstinence and chastity, studied to advance the Catholic religion in Poland and drive out heresy. Thirty-six years after his death he appeared in glittering armour, gallantly mounted, and led the Poles across an impassable river to defeat the Muscovites. In the following year he marched before the Poles in the air and again defeated their enemy. One hundred and twenty years after his death, his body and the rich stuffs in which it was wrapped were found entire and a sweet smell exhaling therefrom.

March 10.

THE FORTY MARTYRS OF SEBASTE suffered at Sebaste in Lesser Armenia, A.D. 320, under the Emperor Licinius. The history of their martyrdom is chiefly remarkable for a novel form of torture devised by Agricola, Governor of the Province. They were exposed naked for three days on a frozen pond outside the walls of the town, in the blast of a bitter north wind, a warm bath being placed nearby. Only one of their number weakened, but he expired as he entered the warm water. His place was taken by the guard, who had been converted in the meantime by a vision. The relics of these martyrs, portions of which reached Constantinople, performed many miracles and healed many sick.

ST. MACKERROGE or KERROCK, bishop in the Province of Levin and Boin in Scotland, A.D. 560, illustrious for miracles. Under his counsel the pious King Congal II. ruled with prudence, zeal, and sanctity. The Scots for a time used his name as their battle-cry, but afterwards changed it for that of St. Andrew. St. Kerroge is sometimes represented in military habit with bent bow and arrow. His name has been given to a ferry (*Port a Chearaig*) and a market for hiring held at Callander, Perthshire, on Mar. 10, O.S. (Mar. 22). This fair is known also as 'tenth-day,' while a rock at the west end of the village is called by his name. "On the Feast of Kerrock every eel is pregnant," is proverbial in Gaelic.

ADDENDA.—THE FIRST SUNDAY IN LENT in one of the Roman Liturgies of 1496 is called *Les Brandons*. In the *Gentleman's Magazine* for 1754 this is taken to refer to the custom among the French peasants of dancing around straw bonfires on this Sunday, and the brandon is said to be one of the sacred dances performed in church choirs as late as the seventeenth century, and only suppressed by ecclesiastical and civil authority after much popular opposition. (*Brandon* = lighted wisp of straw.) That the dance was regarded as an act of worship is shown by the popular Limousin liturgical response, "S. Martial pray for us and we will dance for thee."

Societies and Academies.

London.

Royal Society, Feb. 23.—**Sir Leonard Rogers**: The yearly variations in plague in India in relation to climate: Forecasting epidemics. The seasonal incidence of plague in India depends on monthly variations in mean temperature and humidity, expressed as saturation deficiency, as pointed out by St. John Brooks. Mean monthly temperature variations in hot weather and monsoon periods influence subsequent plague, through high temperatures reducing, and low ones favouring, its prevalence. Saturation deficiency in cold weather as well as in the hot season influences plague incidence, through high saturation deficiency, indicating low relative humidity, reducing prevalence of plague, and vice versa. The great yearly variations in plague can nearly all be explained by the influence of these climatic factors. In the three northern areas, Punjab, United Provinces, and Bihar, four of the six climatic factors become evident before the annual increase of plague from December onwards, and thus allow the more important yearly increases and decreases to be forecast, as a rule. This is also the case to a large extent in Central Provinces. In Deccan, with early increase of plague during monsoon months, forecasts are of less value.

W. S. Patton and **E. Hindle**: The North Chinese species of the genus Phlebotomus. Three species of sandflies were found in North China, namely, *P. major* var. *chinensis*, a variety of *P. sergenti*, and a third species now first described, *P. taianensis*. The first two, in Nature, seem to feed only on human blood; the latter on reptiles and batrachians. The former are of particular interest in connexion with transmission of Leishmania, as in both species the parasite readily develops to the flagellate stage, but only in one of them, *P. major* var. *chinensis*, is there any invasion of the anterior part of the alimentary canal. *P. major* var. *chinensis* normally has only one brood each year. The eggs are usually laid in June, the four larval stages are passed through during summer; the fourth stage larva remains unchanged throughout winter. About mid-May the larva pupates, the adult insect emerging about ten days later. This species only occurs for about six weeks, disappearing in July. *P. sergenti* has a similar life-cycle, but frequently the larvæ complete their development, pupate, and produce another generation in one season. *P. taianensis*, n. sp., resembles the latter in its seasonal incidence, but whereas the two other species are found mainly in houses, this sandfly is especially prevalent in temples and open buildings. In Nature the larvæ of all three species live in cracks in the ground, and are able to withstand freezing. Chinese sandflies have been found only in regions north of the Yangtze Valley. Their distribution, so far as known, agrees with that of Chinese kala-azar, and supports the view that sandflies are responsible for transmission of this disease.

H. Eltringham: On the production of silk by species of the genus Hilara Meig. (Diptera). With an appendix on the habits of the species, by **A. H. Hamm**. The males of certain flies of the genus Hilara (Empididæ) are known to carry silken structures which may or may not contain insect prey or fragments of plants. These structures are transferred to the females just before or at the instant of coitus. The secretion of silk by a mature insect has been hitherto unknown, save in the Embiidæ, Psocidæ, and Hydrophilinæ. The silk of the male Hilara is secreted by numerous unicellular glands situated in the dilated basal tarsi of the anterior legs; the duct of each leads to the base of a short hollow spine, from the apex of which the secretion can be forced to flow, hardening instantaneously on exposure to the air. The cocoons are transferred to the females during flight.

Society of Public Analysts, Feb. 1.—**L. V. Cocks** and **E. Nightingale**: The determination of butter in margarine. Small amounts of sulphuric acid may be volatilised and included in the acids recorded in the Kirschner value, unless special precautions are taken. When the Kirschner value of the butter in a mixture is not known, it is not permissible to state the actual percentage of butter with greater accuracy than between the limits of minus 13 per cent. and plus 24 per cent., both figures being calculated on the reading that would be obtained from the standard graphs for a butter fat with a Kirschner value of 23·5.—**B. S. Evans**: A new method for the separation and determination of small amounts of lead. The method is based on the quantitative deposition of the lead on copper from a cyanide solution containing ammonium oxalate. A percolation apparatus containing copper filings is used. By working in the cold the interference of tin, antimony, zinc, cadmium, and nickel is eliminated; bismuth is deposited, but, in the amounts present in commercial coppers, does not interfere. The deposited lead is converted into sulphate and then into chromate, which is dissolved in nitric acid, and the chromate ion is determined colorimetrically.—**W. R. Schoeller** and **A. R. Powell**: Investigations into the analytical chemistry of tantalum, niobium, and their mineral associates. (10) The separation of silica from the earth acids. Accurate results are obtained by fusing the mixed oxides with bisulphate, extraction of the fused mass with oxalic or tartaric acid, and treatment of the impure silica residue with hydrofluoric acid. (11) The precipitation of titanium by tannin. Tannin produces a red precipitate in oxalic or tartaric solutions of titanium; the precipitation is quantitative in the neutralised solution. Titania interferes with the tannin precipitation of tantalum from niobium, if present in quantities greater than about one-hundredth of the tantalic oxide, by causing a discoloration of the yellow tantalum precipitate.—**J. Reilly** and **P. J. Drumm**: The determination of carvone in dill oil. Carvone is precipitated in the cold from an alcoholic solution of dill oil by means of semi-carbazide hydrochloride and sodium acetate. The carvone semi-carbazone thus obtained melts at 141°-142° C., whilst its isomer (m. pt. 163° C.) is formed if the temperature of the reaction mixture is allowed to rise.—**Norman Rae**: Seasonal variations in the composition of the latex of *Hevea Brasiliensis*. Nitrogen, potash, and phosphoric acid rise to a maximum in February, fall until May, increase somewhat until July, and then fall to August. Leaf fall and renewal of leaves coincide with the fall in March, and maturing of seeds with that of July. The latex seems to be a food reserve used up when leaf growth and seed growth are most actively proceeding.

Linnean Society, Feb. 2.—**Major R. W. G. Hingston**: Nature notes from Mount Everest. Major Hingston accompanied the Mount Everest Expedition of 1924 as medical officer and naturalist. Particular attention was given to the methods by which animals adapt themselves to the special conditions associated with high altitudes. Altitudinal distribution was specially studied. Fishes and reptiles ascended to 15,000 feet. A varied assemblage of mammals, birds, insects, and spiders was collected at 18,000 feet. Moths, butterflies, and humble-bees were carried by wind-currents to 21,000 feet. Birds followed the climbers up to 27,000 feet. The highest plant was taken at 19,000 feet. Small spiders were found living permanently at 22,000 feet.—**W. T. Saxton**: The life-history of Lunularia, with special reference to the archegoniophore and sporophyte. Fertile plants of Lunularia are only rarely found. The course of development of the sporophyte is strikingly different from that of other members of the Marchantiales. The structure of the sessile antheridiophore is similar to that of Fimbriaria and several other Marchantiaceæ. The first divisions in the sporophyte up to the 16-celled stage are quite normal, and the formation of foot and seta from the basal half proceeds as usual, but the divisions in the apical half are exceedingly regular and constant; and the formation of a single group of elongated sporogenous cells, dividing for some time by longitudinal walls only, is a unique feature.

Geological Society, Feb. 8.—**W. J. Pugh**: The geology of the district around Dinas Mawddwy (Merioneth). The Dinas Mawddwy area includes about 22 square miles of country in south-eastern Merioneth. It forms part of the Central Wales Plateau, and is dissected by deep valleys, somewhat modified by glacial action. The rocks consist of mudstones, shales, and slates, with subordinate bands of grit and limestone. They belong to the Bala and the Valentian Series. The area is located on the south-eastern flank of the Harlech Dome, and the fact that the rocks are folded around that great anticline determines the general direction of the strike, which is from south-west to north-east. The faults trend in three directions: (1) north and south; (2) north-east and south-west; (3) north-west and south-east. The north-and-south faults were probably formed at the same time as the folding. The north-west and south-east faults are parallel to the general direction of the dip, which is south-eastward, and they probably belong to a later period of movement than the strike-faulting (south-west to north-east). The rocks are intensely cleaved, and the strike of the cleavage-planes is practically parallel to the general strike of the strata. The cleavage-planes are either vertical or highly inclined south-eastwards. Since they are unaffected by the folding, it is inferred that the cleavage was formed after the folding.

PARIS.

Academy of Sciences, Jan. 23.—**Hadamard**: Repeated operations in the calculus of probabilities.—**A. Cotton**: The automatic regulation of a spectrograph with concave grating. A method of mounting is described which automatically places the slit, grating, and photographic plate in the positions obtained with the mounting of Rowland and of Eagle.—**Charles Moureu** and **Charles Dufraisse**: Autoxidation and antioxygen action. The theory of the catalysis of autoxidation: the mechanism. The authors consider that their views of the mechanism of antioxygen action are not necessarily opposed to the principles of thermodynamics. Independent experimental confirmation of their conceptions is given by the work of H. Gaffron on the addition of oxygen to certain amines in the presence of chlorophyll.—**Gabriel Bertrand** and **Mme. M. Rosenblatt**: The general presence of sodium in plants. The presence of sodium in plants has been a matter of dispute, and this, as the authors point out, has been largely due to the defective methods of chemical analysis employed. The authors depend on the formation of the triple acetate of uranyl, magnesium, and sodium for their sodium estimations, and give results of sodium and potassium determinations in twenty-two plants, those species being selected which have generally been regarded as free from sodium. The results shew that sodium exists in determinable proportions in all plants examined. The ratio potassium to sodium found varies from 729 in potato to 2·05 in peas.—**C. Camichel**, **P. Dupin**, and **M. Teissié-Solier**: The existence of a periodic phenomenon following Poiseuille's law in the flow of a fluid round submerged cylinders.—**Lucien Cayeux** was elected a member of the section of mineralogy in the place of the late E. Haug.—**Paul Mentré**: The projective displacements of two plane bundles with a right line in common.—**Lainé**: The equations $s=f(x, y, z, p, q)$ integrable by the method of Darboux.—**S. Serghiesco**: The number of roots common to several simultaneous equations.—**Henri Milloux**: A property of growth of integral functions.—**Nikola Obrechkoff**: The absolute summation of Dirichlet's series.—**Swyngedauw**: The position of the neutral line in the pulley belt.—**R. Duchêne**: The propagation of combustion in mixtures of hydrocarbons. An application of the photographic method of Mallard and Le Chatelier, with special reference to the phenomena during the early stages of the combustion.—**M. Latour**: An electrocapillary microphone. A conical capillary tube dipping into mercury and covered with a layer of an electrolyte has one wire dipping into the electrolyte and another into the mercury. The apparatus works as a microphone.—**Edmond Rouelle**: Some properties of the frequency demultiplier.—**Henri Marcelet**: The examination of some varieties of cod-liver oil in Wood's light. The light was obtained from a mercury vapour lamp and filtered through a screen allowing light of wave-lengths 3340 A. to 3906 A. to pass. The true fluorescence of cod-liver oil is golden yellow, but this colour is modified in commercial oils, especially the dark varieties.—**B. Cabrera**: Concerning the evolution of the elements.—**Vasilesco Karpen**: Batteries with unalterable electrodes and Carnot's principle. From experiments with an element comprising carbon and platinised platinum electrodes with a solution of soda as electrolyte, the author has obtained results which are in contradiction with the second law of thermodynamics.—**M. Ballay**: A theory of the Ludwig-Soret effect.—**A. Duboin**: The complex silicates of copper. A description of the preparation and properties of the silicates $K_2O, CuO, 4SiO_2$, and $Al_2O_3, 2CuO, 3K_2O, 6SiO_2$.—**Raymond Quelet**: Parabrom-Δ-butenylbenzene.—**A. Mailhe** and **Renaudie**: The formation of hydrocarbons starting with propyl alcohol. A study of the products of the catalytic action of uranous oxide on the vapour of propyl alcohol at 400°-420° C.—**Georges Brus**: The action of chlorine and of bromine on nopinene.—**Pierre Pruvost**: Geological section of the boring of Terrières-en-Bray. This trial boring was carried down to a depth of 1173 metres, and details of the strata exposed are given. No indications of coal or petroleum were found.—**Paul Corbin** and **Nicolas Oulianoff**: The Prarion massif and the complex syncline of Chamonix.—**A. Demay**: The granulitic gneiss of the Pyfara and the Saint-Marcel syncline in the northern Cevennes.—**N. P. Péntcheff**: Researches on the rare gases of some thermal springs in Bulgaria.—**Henri Coupin**: The carbon nutrition of *Rhizopus nigricans*.—**J. Chaine** and **J. Duvergier**: Contribution to the determination of the species of fish of the genus Mugil.—**R. Lutembacher**: The structure of striated muscle from its optical properties. The experiments described suggest that the hypothesis of the presence in striated muscle of two different substances is unnecessary. It has been found possible to make membranes of celluloid or acetylcellulose from which photographs have been obtained, both in natural and polarised light, resembling the microphotographs obtained with muscle.—**R. Douris** and

J. **Beck**: The mode of action of reagents in the serum diagnosis of syphilis. The influence of pH.—**N. Bezssonoff**: The food regime based on oats and egg yolk and the duality of vitamin C.—**Swigel Posternak** and **Théodore Posternak**: A natural, optically active inosite-tetraphosphoric ester.—**H. Bierry** and **M. Kollmann**: The pancreas and the testicle in the course of polyneuritis in birds.—**Marage**: Deafness and musical composition.

CALCUTTA.

Asiatic Society of Bengal, Jan. 2.—**R. B. S. Sewell**: Prehistoric animal remains from the ancient Indian city of Mohenjo-daro, Sind. In the course of excavations at Mohenjo-daro in Sind, the Archæological Survey of India discovered a number of more or less fragmentary animal remains. Owing to the large amount of saltpetre in the soil, these bony remains rapidly deteriorate, and in the deeper, and presumably older, levels, comparatively few animals can be identified from these fragments. In all, some thirty species of animals, ranging from coral to the Mammalia, have been identified. Some of these were undoubtedly living in this region at the time when Mohenjo-daro was a flourishing city, but in other cases the remains, such as shells or horns, appear to have been brought from distant areas in the process of trade. This is the first find of prehistoric animal life in an Indian city.

WASHINGTON, D.C.

National Academy of Sciences (*Proc.*, Vol. 13, No. 12, December).—**G. W. Stewart**: X-ray diffraction in liquids: saturated normal fatty acids, isomers of primary normal alcohols, and normal paraffins. (*a*) Normal fatty acids. The lateral separation of the parallel collinear chains is 4·55 A.; the longitudinal spacing of the diffraction centres increases 2·00 A. for two carbon atoms, one for each of two molecules. (*b*) Isomers of primary *n*-alcohols. The attachment of CH_3 as a side branch alters the 'diameter' by 0·6 A., of OH by 0·4 A., of both by 0·65 A. (*c*) Normal paraffins. Lateral separation of molecules is approximately 4·6 A. The results all suggest the importance of molecular space array (cybotaxis) in liquids.—**Jared Kirtland Morse**: The structure and dimensions of the benzene ring. A model consisting of cubes having corners shared in common is put forward: such a model on a scale of 2 in. = 1 A. has been constructed. Twelve cube corners (electron positions) are on the surface of a sphere of radius 1·155 *R*, six cube centres (carbon nuclei) on a concentric sphere of radius 1·394 *R*, and the remaining twenty-four cube corners on another concentric sphere of radius 2·134 *R*, where *R* is the radius of the carbon atom.—**Frank Peat Goeder**: The space group of potassium, rubidium, and cæsium sulphates. From an examination of Laue photographs of the rhombic bipyramidal or holohedral crystals of the anhydrous salts, the space group is 2 *Di* – 13, (V_h^{13}).—**S. C. Wang**: The diamagnetic susceptibility of hydrogen molecule and of helium in the new quantum mechanics. The energy values obtained by the Ritz method from the approximate ψ functions developed agree fairly well with spectroscopic results.—**J. R. Oppenheimer**: On the quantum theory of the polarisation of impact radiation. Taking into account the spin of the impacting electron, the Heisenberg resonance principle, and the perturbing energy, it is shown that the polarisation diminishes with decreasing electronic velocity, changes sign at about 200 volts, increases to a maximum near the resonance potential and afterwards approaches zero. This is in accord with experimental evidence.—**S. Lefschetz**: The residual set of a complex on a manifold and related questions (second note).—**Ernest P. Lane**: Power series expansions in the neighbourhood of a point on a surface.—**Marston Morse**: The analysis and analysis situs of regular *n*-spreads in $(n+r)$-space.—**H. L. Rietz**: On certain properties of frequency distributions of the powers and roots of the variates of a given distribution.—**Matilda Moldenhauer Brooks**: The penetration of methylene blue into living cells. This dye penetrates into the sap of Valonia, but is gradually oxidised when the sap is exposed to air. The equilibrium quantity of dye in the sap is unaffected by the temperature and hydrogen ion concentration of the external solution, but its rate of entry decreases with decrease of temperature and increases with increase of hydrogen ion concentration within limits.—**Leonell C. Strong**: Studies on the effect of potassium alum–hydrochloric acid solutions on the growth and fate of neoplastic tissue (2). Result obtained on a rapidly growing transplantable sarcoma of the mouse. With this non-specific tumour, no slowing-up of the rate of growth could be observed with certainty.—**Henry B. Ward**: The influence of a power dam in modifying conditions affecting the migration of the salmon. Sockeye or red salmon spawn near the headwaters of coastal streams. In the Baker River, State of Washington, their course is determined by the impulse to 'buck' the current and, when a choice of waters is possible, as at the outflow of a tributary, they choose the cooler stream. A power dam 260 ft. high bars the normal salmon route up the Baker River; a fisher ladder and cable hoist have been installed to carry the salmon to the upper waters. Some fish exhaust themselves in the tail-race of the power-house, while others fight against the dam. Of those that are lifted over, only a portion go on to the headwaters. The dam has created a still lake with high surface temperature and cold depths with little current. This alters entirely the migratory conditions and may influence the type of fish.—**Paul Slavenas**: A note on the triple system, λ Tauri.—**Hudson Hoagland**: Quantitative aspects of tonic immobility in vertebrates. Measurements of the duration of 'death feigning' or tonic immobility in the lizard Anolis at carefully maintained temperatures indicate two independent reactions, one at 5°-35°, and the other at 5°-20° C., of a chemical nature. The presence is suggested of two independent inhibitory hormones which inhibit impulses from higher nervous centres, but pass impulses from tonic centres to the muscles.—**Roland C. Travis** and **Raymond Dodge**: Sensori-motor consequences of passive rotary and rectilinear oscillation of the body. The authors were tested on moving platforms, and the responses of the hands (an effort to keep the hands stationary) were observed. When blindfolded, compensatory movements were practically proportional to the acceleration. The higher the frequency of rectilinear oscillation, the more adequate was the perception of motion and its direction. The order of sensitivity of receptors for rectilinear oscillations is visual, kinæsthetic, and vestibular.—**Barbara Stoddard Burks**: Foster parent–foster child comparisons as evidence upon the nature–nurture problem. The results of Stanford-Binet intelligence tests of 200 sets of foster parents and foster children were compared with the results obtained from 100 sets of true parents and true children, and data as to the cultural, educational, and material aspects of the homes were considered. The contribution of home environment to intelligence is rated at 17 per cent.; environment may in exceptional cases raise or lower the intelligence quotient (I. Q.) by 20 points.—**Herman C. Ramsperger**: The thermal and photochemical decomposition of azo compounds and the problem of reaction rates.

CATALOGUE.

Sands, Clays and Economic Minerals for all Industrial Purposes. Fourth edition. Pp. 32. (Chatteris: Algernon Lewin Curtis.)

Diary of Societies.

SATURDAY, MARCH 3.

ROYAL INSTITUTION OF GREAT BRITAIN, at 3.—C. Dodgson: The Life and Work of Albrecht Durer (II.).

BRITISH PSYCHOLOGICAL SOCIETY (at Royal Anthropological Institute), at 3.—Dr. Saidullah: A Note on the Theory of 'Shape' in the Light of some Recent Experimental Work.—E. R. Clarke: The Evaluation of the Heterogeneity of the Binet Tests and the Resulting Fallacy of the I.Q.

INSTITUTE OF BRITISH FOUNDRYMEN (Lancashire Branch) (at College of Technology, Manchester), at 4.—Prof. C. H. Desch: Crystallisation in Non-ferrous Castings (Lecture).

HULL ASSOCIATION OF ENGINEERS (at Technical College, Hull), at 7.15.—A. W. Purchas: Theory and Practice in the Engine and Boiler Rooms.

MONDAY, MARCH 5.

ROYAL SOCIETY OF EDINBURGH, at 4.30.—Prof. H. G. Cannon: On the Feeding Mechanism of the Shrimp, *Chirocephalus diaphanus*.—Dr. C. H. O'Donoghue and Miss Eileen (Hulman) Abbott: The Blood Vascular System of the Spiny Dogfish, *Squalus acanthias*, Linné, and *Squalus sucklii*, Gill.—Dr. S. Williams: Sporangial Variation in the Osmundaceæ.—Dr. C. W. Wardlaw: Size in Relation to Internal Morphology. No. 3, The Vascular System of Roots.—J. Caldwell: Translocation.

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.—General Meeting.—At 5.15.—Prof. E. Schrodinger: Wave Mechanics (I.).

INSTITUTION OF AUTOMOBILE ENGINEERS (Bristol Centre) (at Merchant Venturers' Technical College, Bristol), at 6.45.—G. L. Ensor: Notes on the Single Sleeve-Valve Principle.

INSTITUTE OF METALS (Sheffield Local Section) (jointly with Kindred Societies) (in Non-Ferrous Section, Applied Science Department, Sheffield University), at 7.30.—Dr. S. Z. de Ferranti: Electricity in the Service of Man.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.—G. H. Jack: Ancient Bridges.

SOCIETY OF CHEMICAL INDUSTRY (London Section) (at Chemical Society), at 8.—Prof. G. T. Morgan, R. Taylor, and T. J. Hedley: Syntheses under High Pressure.

SURVEYORS' INSTITUTION (at Institution of Civil Engineers), at 8.—P. J. Waldram: The Estimation of Damage in Ancient Lights Disputes.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 8.30.—D. R. G. Cameron: Across the Sahara from Kano to Warghla.

INSTITUTION OF THE RUBBER INDUSTRY (London and District Section) (at Engineers' Club, Coventry Street, W.1).—L. J. Lambourn: Methods used for Determining Abrasion with Particular Reference to the Relation between Road Performance and Laboratory Results.

TUESDAY, MARCH 6.

ELECTRICAL ASSOCIATION FOR WOMEN (at Oxford Circus House, 245 Oxford Street, W.1), at 3.—M. A. Hussey: The Home Electric Laundry.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, at 5.—Dr. F. A. E. Crew: Individual, Familial, and Racial Differences in respect of Immunities and Disease Resistance (Milroy Lectures) (II.).

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.15.—Prof. J. S. Huxley: The Behaviour of Animals (III.).

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—Dr. H. Harold Scott: (*a*) Report on the Deaths occurring in the Society's Gardens during the year 1927; (*b*) Carcinoma of the Tonsil in a Common Wolf (*Canis lupus*).—Major M. Connolly: On a Collection of Land and Freshwater Mollusca from Southern Abyssinia.—Enid K. Sikes: The External Morphology and Life-history of the Coccid Bug *Orthezia urticae* Linn.

INSTITUTION OF CIVIL ENGINEERS, at 6.

LONDON NATURAL HISTORY SOCIETY (at Winchester House, E.C.), at 6.30.—J. C. Robbins: Hibernation of Insects.—R. W. Hale: Beaks and Bills of British Birds.

INSTITUTION OF ELECTRICAL ENGINEERS (North Midland Centre) (at Hotel Metropole, Leeds), at 7.—D. S. Munro: Modern Electric Wiring, particularly as applied to Small Houses.

INSTITUTION OF ELECTRICAL ENGINEERS (North-Western Centre) (at Engineers' Club, Manchester), at 7.—E. C. McKinnon: Storage Batteries in relation to Modern Supply of Electric Lighting and Power.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN (Pictorial Group), at 7.

INSTITUTION OF AUTOMOBILE ENGINEERS (Coventry Graduates' Meeting) (at Broadgate Café, Coventry), at 7.15.—A. E. Collins: The Problem of Selling Cars.

INSTITUTE OF METALS (North-East Coast Local Section) (at Armstrong College, Newcastle-upon-Tyne), at 7.30.—Annual General Meeting and Exhibition of Metallurgical Preparations and Products.

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (Middlesbrough Branch) (at Cleveland Scientific and Technical Institution, Middlesbrough), at 7.30.—C. H. Cooke: Lubrication.

INSTITUTION OF AUTOMOBILE ENGINEERS (at Royal Society of Arts), at 7.45.—Dr. F. W. Lanchester: Automobile Steering Gear—Problems and Mechanism.

ROYAL SOCIETY OF MEDICINE (Orthopædics Section), at 8.30.—H. Platt and others: Discussion on The Treatment of Acute Osteomyelitis.

INSTITUTION OF THE RUBBER INDUSTRY (Liverpool Section) (in Common Hall, Dale Street, Liverpool).—R. M. Fitzpatrick: Rubber Footwear Manufacture.

WEDNESDAY, MARCH 7.

INSTITUTE OF METALS (Annual General Meeting) (at Institution of Mechanical Engineers), at 10 A.M.—Presidential Address.—S. Beckinsale and H. Waterhouse: The Deterioration of Lead Cable Sheathing by Cracking, and its Prevention.—Dr. M. Haas: The Dilatometric Study of Light Metals.—Dr. Ezer Griffiths and F. H. Schofield: The

Thermal and Electrical Conductivity of Some Aluminium Alloys and Bronzes.—R. Chadwick: The Constitution of the Alloys of Magnesium and Zinc

At 2.—H. O'Neill. Historical Note on Density Changes caused by Cold-working of Metals.—Major F. S. Grimston. Season-Cracking of Small Arms Cartridge Cases during Manufacture.—F. Hargreaves: The Ball Hardness and the Cold-working of Soft Metals and Eutectics.—W. L. Kent: The Behaviour of Metals and Alloys during Hot-Forging.—W. A. Cowan: Minute Shrinkage Cavities in Some Cast Alloys of Heterogeneous Structure.—W. A. Cowan: Note on the Composition of Old Roman Lead.

Royal Society of Medicine (History of Medicine Section), at 5.—Dr. R. Hutchison. A Biographical Note on Sir James Wylie, Bart., M.D., a Medical Adventurer.—F. Prescott: Louis Pasteur and Fermentation.

Royal Institution of Great Britain, at 5.15.—Prof. E. Schrodinger: Wave Mechanics (II.)

Geological Society of London, at 5.30.—Hilda K. Cargill, Dr. L. Hawkes, and Julia A. Ledeboer: The Major Intrusions of South-Eastern Iceland.

Institution of Electrical Engineers (Wireless Section), at 6.—G. W. N. Cobbold and A. E. Underdown: Some Practical Applications of Quartz Resonators.

Society of Chemical Industry (Glasgow Section) (at 39 Elmbank Crescent, Glasgow), at 7.—W. MacLaren: The Principles of Coal Cleaning.

Institution of Electrical Engineers (South Midland Centre) (at Birmingham University), at 7.—D. S. Munro: Modern Electric Wiring, particularly as applied to Small Houses.—A. J. Milne and R. H. Rawll: The Domestic Applications of Electricity.

Institution of Electrical Engineers (Tees-Side Sub-Centre) (at Cleveland Technical Institute, Middlesbrough), at 7.—D. T. Smout: Electric Welding

Glasgow University Alchemists' Club (Annual Meeting) (at Glasgow University), at 7

Institution of Heating and Ventilating Engineers (at Caxton Hall, Westminster), at 7.—H. R. Hiscott: The Manufacture of Malleable Iron Pipe Fittings.

Society of Chemical Industry (Nottingham Section), at 7.30.—F. S. Sinnatt: The Formation and Structure of Cenospheres; a Study of the Carbonisation of Coal in the Form of Particles.

Society of Public Analysts and other Analytical Chemists (Annual General Meeting and Ordinary Meeting) (at Chemical Society), at 8.—Presidential Address.—Prof. T. P. Hilditch: Composition of the Fatty Acids present as Glycerides in Elasmobranch Oils.—R. T. Thomson: Behaviour of Indicators in the Titration of Ammonia, Sodium and Calcium Phosphates, the Methylamines, Pyridine Bases and Boric Acid.—H. R. Jensen. Cacao Tannin.

Royal Institute of British Architects, at 8.—J. H. Jarman: General Building Materials (Lecture)

Royal Society of Arts, at 8.—Dr. J. H. Jeans: Some Wider Problems of Cosmogony (Trueman Wood Lecture).

Royal Society of Medicine (Surgery Section), at 8.30.—Dr. T. de Martel and others: Discussion on Colectomy.

Royal Microscopical Society (Biological Section).

THURSDAY, March 8.

Institute of Metals (Annual General Meeting) (at Institution of Mechanical Engineers), at 10 A.M.—G. L. Bailey: The Influence of Dissolved Gases on the Soundness of 70 : 30 Brass Ingots.—Dr. A. L. Norbury: The Effect of Quenching and Tempering on the Mechanical Properties of Standard Silver.—Dr. J. N. Friend and W. E. Thorneycroft: An Example of Roman Copper 'Soldering' and Welding from Uriconium.—Dr. J. N. Friend: The Relative Corrodibilities of Ferrous and Non-Ferrous Metals and Alloys. Part I. The Results of Four Years' Exposure in the Bristol Channel.—Dr. T. E. Allibone and C. Sykes: The Alloys of Zirconium. I.—Dr. T. Matsuda: On the Quenching and Tempering of Brass, Bronze and Aluminium-Bronze.

London Mathematical Society (at Royal Astronomical Society), at 5.—Prof. A. E. H. Love: Biharmonic Analysis, especially in a Rectangle, and its Applications to the Theory of Elasticity (Lecture)

Royal Society of Medicine (Balneology Section), at 5.—Dr. F. Fox and others: Discussion on The Value of Marine Health Resorts, with a Special Reference to Children.

Royal College of Physicians of London, at 5.—Dr. F. A. E. Crew: Individual, Familial, and Racial Differences in respect of Immunities and Disease Resistance (Milroy Lectures) (III.).

National Institute of Industrial Psychology (at Royal Society of Arts), at 5.15.—Investigators of the Institute. The Attitude of Employees towards the Institute's Investigations

Royal Institution of Great Britain, at 5.15.—Dr. J. J. Fox: Optics and Chemistry (I.).

British Psychological Society (Education Section), at 6.—R. R. Dobson. Report of an Inquiry into the Attitude of Local Authorities towards Mental Tests

Royal Photographic Society of Great Britain (Colour Group) (Annual Meeting), at 7.

Society of Dyers and Colourists (Midlands Section) (at University College, Nottingham), at 7.30.—C. Mitchell: Further Work with Vat Dyes

Optical Society (at Imperial College of Science) (Annual General Meeting), at 7.30.—Dr. R. S. Clay: The Stereoscope, Illustrated by Demonstrations and Exhibits of Early Apparatus and Slides (Presidential Address).

Institution of Electrical Engineers (Dundee Sub-Centre) (at University College, Dundee), at 7.30.

Institution of Electrical Engineers (Irish Centre—Dublin) (at Trinity College, Dublin), at 7.45.—Dr. S. Z. de Ferranti: Electricity in the Service of Man (Faraday Lecture).

Institution of Mechanical Engineers (Cardiff Branch).—W. K. V. Phillips: Engineering in the Cement Industry.

Oil and Colour Chemists' Association (at 30 Russell Square, W.C.1).—E. W. J. Mardles: Notes on Aeronautical Paints and Varnishes.

FRIDAY, March 9.

Royal Society of Arts (Indian Meeting), at 4.30.—Col. I. A. E. Edwards: The Air Routes of India.

Physical Society (at Imperial College of Science), at 5.—Sir J. J. Thomson: On Electrodeless Discharge through Gases (Guthrie Lecture).

Malacological Society of London (at Linnean Society), at 6.

North-East Coast Institution of Engineers and Shipbuilders (at Mining Institute, Newcastle-upon-Tyne), at 6.—J. S. Brown: Measurement of Power.

Junior Institution of Engineers (Informal Meeting), at 7.30.—B. S. Huntingford: Air Compressors.

Institute of Metals (Sheffield Local Section) (in Non-Ferrous Section, Applied Science Department, Sheffield University), at 7.30.—W. R. Barclay: Special Alloys in relation to the Corrosion Problem.

Oil and Colour Chemists' Association (Manchester Section) (at Milton Hall, Deansgate, Manchester), at 7.30.—Dr. J. N. Friend: Researches on the Preservation of Iron and Steel with Paint

Royal Institution of Great Britain, at 9.—Prof. E. A. Milne: The Sun's Outer Atmosphere.

Institution of Electrical Engineers (South Midland Centre) (jointly with Midland Centres of Institutions of Civil and Mechanical Engineers) (at Birmingham)

Institution of Mechanical Engineers (Manchester Branch) (jointly with Manchester Association of Engineers).—N. Greenhalgh: Examples of Modern Tool Room Practice.

SATURDAY, March 10.

Royal Institution of Great Britain, at 3.—Sir Ernest Rutherford: The Transformation of Matter (I.)

PUBLIC LECTURES.

SATURDAY, March 3.

Horniman Museum (Forest Hill), at 3.30.—J. E. S. Dallas: A Naturalist at Land's End.

MONDAY, March 5.

Royal Institution of Great Britain, at 5.15.—Prof. E. Schrodinger: Wave Mechanics. (Succeeding Lectures on Mar. 7, 12, and 14.)

University of Leeds, at 5.15.—Sir John Russell: Science and Food Production.

East Anglian Institute of Agriculture (Chelmsford), at 7.—Principal W. A. Stewart: The Production of Baby Beef.

TUESDAY, March 6.

Bedford College for Women, at 5.15.—Prof. E. B. Poulton: Recent Discoveries throwing New Light on some of the Commonest Insects.

University College, at 5.15.—J. Ramsbottom: The Evolution and Classification of Fungi. (Succeeding Lectures on Mar. 13 and 20.)

University of Leeds, at 8.—Prof. P. C. Buck: The Meaning of Progress in Music

WEDNESDAY, March 7.

Medical School, Leeds, at 3.30.—Sir Berkeley Moynihan: Introduction to a Series of Lectures on Cancer.

Royal Institute of Public Health, at 4.30.—Dr. G. R. Lynch: Some Problems in Medico-Legal Practice

King's College, at 5.30.—Sir R. A. Sampson: In what Degree is Science True?

University College, at 5.30.—Dr. A. Mansbridge: The Citizen and the Librarian.

THURSDAY, March 8.

Stuart Hall, St. Andrew's Hall Plain, Norwich, at 8.—F. W. Alexander: The Value of Sunlight (Chadwick Lecture).

FRIDAY, March 9.

Armstrong College, Newcastle-upon-Tyne, at 8.—Prof. R. Robinson: The Relation of Some Plant Products to the Simple Sugars and the Amino Acids (Bedson Lecture)

SATURDAY, March 10.

Horniman Museum (Forest Hill), at 3.30.—C. Darrell Forde: The First Metal-Workers.

CONFERENCES.

March 5 and 6.

German Society for Researches on the Circulation (at Cologne)

March 8 and 9.

Institution of Chemical Engineers (at New Princes' Restaurant, S.W.1).

Thursday, March 8.

At 5.—Prof. B. W. Holman: The Theory of Magnetic Separation

At 8.—Dr. B. Moore: The Combustion of Powdered Coal.

Friday, March 9.

At 11.30 A.M.—Sixth Annual Corporate Meeting.

At 12 noon.—President's Address: The Economics of Power as Applied to Chemical Engineering.

At 2.15.—Dr. O. Spengler: The Treatment of Effluents from Beet Sugar Factories.

March 28 to 31.

German Balneological Congress (at Baden, near Vienna).

SATURDAY, MARCH 10, 1928.

Popular Science.

POPULAR science is a phrase which almost inevitably conjures visions of Pepper's ghost, unpleasant smells, a loud bang, and a disapproving mother. Not only in chemistry and physics, but also in psychology, sociology, and economics, the term suggests a superficial acquaintance with the more amusing manifestations of natural phenomena or with some arguable thesis concerning political affairs rather than any widespread understanding of the relation between cause and effect. Nevertheless, there is a general lay interest in the march of science, and very laudable attempts have been made, and continue to be made, to keep the populace informed of the trend of its progress, its rate, its direction, its practical effects, and something of the spirit permeating its body of serving men and women. Such a presentation demands painstaking and prolonged effort. The material must not be inaccurate, yet it must necessarily be indefinite, it must be attractive but not sensational, dignified but not high-brow. It must not be presented in its native language, but in that of everyday speech; it must indicate some practical advantage or it must positively refrain from suggesting any such mundane possibility, according as it is intended to be read before or after dinner.

We need not debate the desirability of recording the progress of scientific investigation and of discussing cognate matters in such a way as appeals to the 'average' man. Obviously, if the task is not undertaken there can be little public appreciation of or sympathy with the objects to which the workers have devoted their labours, neither can there be full support in the provision of conditions necessary for the fruition of their efforts. Could one, for example, imagine an unenlightened community establishing a Ministry of Health, or a Department of Scientific and Industrial Research, or even a Broadcasting Corporation? It does not necessarily follow, of course, that progress is any the more rapid on account of public interest, especially when the problem happens to be one which may admit of confusion by the articulate assistance of partially informed critics, but it is indisputable that encouragement and provision are much more likely to be the outcome of knowledge than of ignorance. Apart from such a consideration, most readers of the general press seek to know more of the world around them, whether physical, moral, ethnological, or industrial, provided that the effort accompanying the stimulation of their interest is not too noticeable. If science is displayed for their benefit, it is not intended that they should be creative investigators; if poetry, that they should rush into verse. Besides, ignorance of natural laws, as of other laws, is no insurance against the regrettable consequences which may arise from their neglect.

The translation of scientific news—nowadays so enormous in its bulk—into suitable language, and its condensation to comparatively minute dimensions, are undertaken in a systematic manner in the United States of America by an organisation known as Science Service, Inc., directed by Dr. E. E Slosson, and functioning under the auspices of the National Academy of Sciences, the National Research Council, and the American Association for the Advancement of Science. This organisation publishes daily science news bulletins, and a weekly summary of current science entitled the *Science News-Letter*, in which current events, scientific discoveries, and résumés of progress, together with broadly-drawn reports of the proceedings of scientific conventions, are recorded in simple terms. In addition, there is compiled a weekly digest, intended to present the cream of the week's scientific news, which is regularly used by more than twenty broadcasting stations in the United States.

Fortunately, in Great Britain there is little fear that discoveries might be announced to the listening public in a manner savouring of sensationalism, or that accounts of scientific affairs might be so rendered as to appear ludicrous to the initiated, for the policy in this respect of the British Broadcasting Corporation and of its predecessor company has been exemplary. We are, however, familiar with the result of excursions by otherwise competent journalists into spheres with which they are not familiar; indeed, the distaste for publicity which is usually ascribed to undue modesty might, if the truth were known, quite possibly often be traced simply to a fear of misrepresentation. The American press is now able, however, to rely on telegraphic news 'stories,' prepared by the managing editor of Science Service, Mr. Watson Davis, and the members of his specialist staff, so that their reports of the proceedings of conferences and conventions shall be well-balanced and accurate, without losing their attractiveness as items of news.

In Great Britain there is, of course, fairly adequate publication and survey of the results of research, such publication being intended for the use of the scientific population itself, and being normally directed by members of that fraternity, but we seem to lack a widespread sense of the importance of an appeal to the non-specialist members of the community as part of their ordinary daily culture, an appeal which must, to be worth while, be sponsored by the most notable members of the professions, and to be effective by the more journalistically-minded among them. There is, after all, no valid reason why the dissemination of knowledge beyond the confines of schools and colleges, provided it is carried out with scrupulous honesty, dignity, and restraint, should not be acknowledged to be as valuable a social service as the collection and arrangement of the knowledge itself. True, this view has been given practical effect in certain influential sections of the British lay press by acknowledged authorities in a number of the sciences, but apart from one or two publications of admitted standing, there is little organised continuous effort in this direction. An attempt was made a couple of years ago to secure the interest of scientific societies and institutions in Great Britain in the establishment of a science publicity service, but the response was so disappointing that the scheme was abandoned.

Dr. E. E. Slosson, in a recent address before the American Association for Adult Education, made the somewhat surprising statement that archæology and astronomy—essentially remote and unpractical—head the list of the sciences in order of popular interest, and that the essentially practical sciences are low in the list. He ascribes this, probably correctly, to the same cause as that operating in the selection of, say, 'Futuristic Art' as a subject of study in a women's club rather than 'Domestic Economy.' He declares that scientific workers have been too humble and too modest in claiming credit for what they have done and what they can do in the control of human affairs, but have allowed statesmen, writers, and financiers to take all the praise for the advance in civilisation and the amelioration of living conditions that were really due to scientific research. If we look at the matter from the point of view of the wealth of nations, as Dr G. E. Hale, the honorary chairman of the National Research Council, has recently done in *Harper's Magazine*, it is clear enough that the business of men of science is to help to guide mankind as well as to serve it. That is to say, if a scientific orientation can more universally be associated with moral and religious convictions in the equipment of the human mind, there will be less danger of the wicked and unscrupulous misuse of scientific power, less point in arguing the prohibition of poison gas, and an extension of that wider fraternal patriotism which distinguishes scientific international relations.

Magnetic Properties of Single Crystals of Zinc and Cadmium.

RECENT investigators have studied the thermal expansion, the electrical resistance, the elastic constant, the thermoelectric and the photoelectric effects of single crystals of metals, but up to the present few accurate results have been obtained for the fundamental para- or diamagnetic properties of such metals.

Last year the susceptibilities of the alkali metals were studied, and it was thought of interest to extend this investigation to a study of the elements of the second column of the periodic system. When these elements were studied previously (Honda and Owen), metals in the form of an isotropic aggregate of crystals were used. As zinc and cadmium form crystals of the hexagonal system, the value of the magnetic susceptibility parallel to the crystallographic axis would be expected to differ from its value in a perpendicular direction.

In making crystals for these experiments, the method described by Bridgman was used. He found that for cadmium and zinc the preferred manner of growth was with the basal plane parallel or perpendicular to the axis of the cylinder. Under a rough optical examination, the crystals used in the experiment referred to appeared to be orientated with the basal plane parallel to the axis of the cylinder.

To study the susceptibility, the crystals were suspended vertically from one arm of a balance so that the lower end hung between the poles of an electromagnet, and weighings were taken in the presence and absence of a known magnetic field. The crystal was rotated through 360° about a vertical axis, readings being taken every 15°. The results obtained are shown in the accompanying diagram (Fig. 1). At the position of maximum and minimum effect, readings were taken for a range of field from 5000 to 12,000 gauss, and corrections for iron impurities were made according to the method given by Owen. By this method, the amount of free iron contained in the metal was found to be of the order of $0 \cdot 5 \times 10^{-6}$ gm. of iron per gram of metal. The specific susceptibilities obtained in this manner were, for zinc, $-0 \cdot 183 \times 10^{-6}$ in a direction parallel to the principal axis of the crystal, and $-0 \cdot 147 \times 10^{-6}$ in a direction perpendicular to this. For cadmium, these values were $-0 \cdot 276 \times 10^{-6}$ and $-0 \cdot 169 \times 10^{-6}$. The values given by Owen, obtained from coarse-grained crystals, were, zinc $-0 \cdot 155 \times 10^{-6}$ and cadmium $-0 \cdot 18 \times 10^{-6}$.

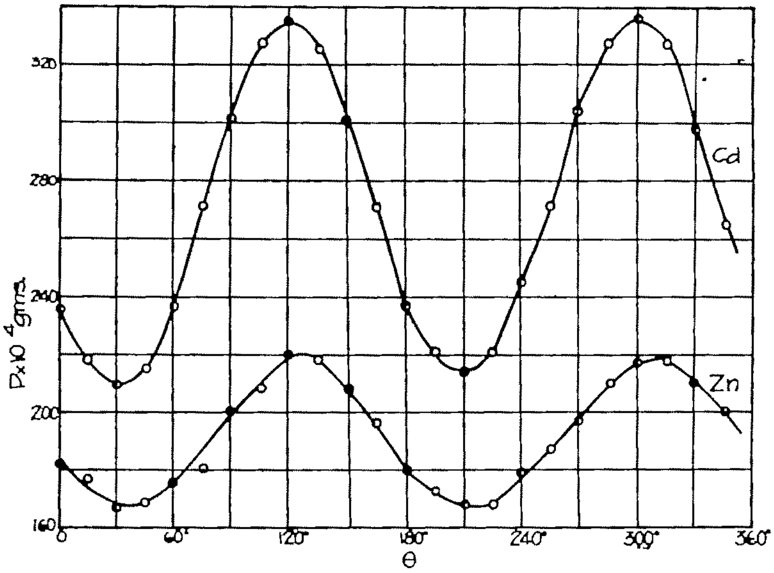

FIG. 1.

It is intended to study a still larger number of crystals and to investigate the influence of low temperatures upon their magnetic susceptibility.

One of us, Elizabeth Cohen, has been enabled to co-operate in this investigation through the award to her of a studentship by the National Research Council of Canada.

Passivity and Protective Oxide Films.

IN NATURE of Feb. 11 (p. 222) it is stated that "An X-ray examination of finely divided iron, nickel, and chromium, conducted by F. Krüger and E. Nahring at Greifswald, has shown conclusively that films of oxide thicker than 10^{-7} cm. are not present on the surface of a passive metal." Lest a wrong impression be gained from this statement, I would venture to add a few remarks on the factors which determine the thickness of protective films.

The film produced by oxidising agencies on metals necessarily ceases to thicken as soon as it becomes sufficiently protective to exclude the oxidising agent. Recent work (*Jour. Chem. Soc.*, 1020; 1927) has pointed to the fact that, on freshly abraded iron, the considerable thickening of the film experienced proceeds through the production of cracks due to the internal stresses left by the abrasion; only when this cracking of the film has ceased will the thickening come to an end. Since a cracked film produces no passivity, coarsely ground metal requires a longer time to become passive than finely ground metal, and develops a thicker film, especially if substances be present in the solution which are capable of penetrating the smallest cracks (*e.g.* chlorine ions). The films obtained from abraded specimens attain thicknesses of the order 10^{-6} cm., and can be isolated from their basis and studied. In the presence of a regulated amount of penetrating anions, the thickness may come to exceed 4×10^{-6} cm., and the films will then give rise to interference tints. Great thickening is only to be obtained under conditions which render the material less perfectly protective, and there is naturally some danger that the film will break down altogether. Under suitable conditions, however, considerable thicknesses may be reached; the writer has quite recently prepared some specimens showing the complete sequence of interference tints right up to the late second-order colours; although produced at room temperature, the sequence of colours is the same as that of the 'temper colours' obtained at high temperatures, and the tints are, on the whole, brighter.

The tiny particles of metal used by Kruger and Nähring were presumably almost free from internal stresses. On stress-free metal there will be practically no cracking of the film, and the film will stifle its own growth as soon as it is continuous over the whole surface. There is no reason to think that the thickness will come to exceed 10^{-7} cm. In any event, it is not probable that these very thin films would cause oxide-lines. The work of Kohlschütter and Krahenbühl (*Zeit. Elektrochem.*, **29**, 570; 1923) on films of silver halides suggests that such films only assume their proper crystalline structure when they reach a much greater thickness; a 'pseudomorphic' stage precedes the 'idiomorphic' stage. Krüger and Nähring's attempt to check their method by studying mixtures of granular oxide with granular metal gives no indication of the behaviour of oxide-coated metallic granules.

Indeed, the main result of the research is to show how very unsuitable is the X-ray method for this particular purpose. The authors appear extremely satisfied at recognising the oxide lines in nickel powder mixed with 2 per cent. of nickel oxide. Chemical analysis would, of course, detect a far smaller oxide-content, and (unlike the X-rays) would detect it equally well whether the oxide be vitreous or crystalline, or whether it be pseudomorphic or idiomorphic. It is a little difficult to understand why—in a research where a negative result was probably expected—the authors should have chosen to adopt the less sensitive method. While, however, the X-rays appear unsuited to deal with a phenomenon confined to the surface layers, light rays, to which the metal is relatively opaque, give valuable information. It is often stated that the optical properties of passive iron are identical with those of active iron. This has recently been shown to be untrue by Freundlich, Patscheke, and Zocher (*Zeit. Phys. Chem.*, **128**, 321; 1927: **130**, 289; 1927), who have found that, on admitting oxygen to the surface of pure iron mirrors, a sudden change occurs in the phase relations of the two components of elliptically polarised light reflected from the metal; this change they attribute to an oxide film. At the same time—and, no doubt, owing to the same cause—the chemical activity suddenly falls off, the iron becoming unaffected by nitric acid of concentrations which have a marked action upon the iron mirrors if introduced *before* the admission of oxygen.

'Air-passivity' (*i.e.* marked change in chemical properties of iron, brought about simply by exposure to air or oxygen) appears to be a property of the pure metal. It is not shown well by the commercial varieties of iron (other than chromium steels), probably because the oxide-film produced by gaseous oxygen has discontinuities at the junctions of the different phases present. The phenomenon is, however, displayed both by Freundlich's iron mirrors, produced by the decomposition of the carbonyl, and also by the electrolytic iron used in the writer's own work. It has been somewhat satisfactory to find that the quite independent study of the two materials —obtained by two totally different methods and in forms quite dissimilar externally—has led to concordant results and identical conclusions.

ULICK R. EVANS.

University Chemical Laboratory,
Cambridge.

The Trail of the Germ-plasm.

IN his brilliant analysis of the phenomena of growth, T. B. Robertson ("Chemical Basis of Growth and Senescence," 1923) starts with the assumption that growth phenomena can be likened to certain chemical reactions which are subject first to an acceleration due to catalysis and in a later phase diminished by the products formed in the course of the reactions (autocatalysis). Growth phenomena so closely resemble such reactions in so many cases cited, that Robertson gradually assumes that his premise is correct, and finally ends in accepting the proof accumulated. Let the thesis be accepted as a working hypothesis. The two most awkward phenomena to bring in line with the hypothesis were found to be the carrying on of the germ-plasm intact in the course of development to the adult gonad, and cancer-like growths. In connexion with this hypothesis the following observations on germ-plasm may be helpful.

With regard to the trail of the gonadial germ-plasm in ontogeny a great deal has been written, but relatively very little determined. In a recent search among the literature of the subject, I tried to find out whether mitoses had *ever* been recorded in an adult gonadial epithelium, and found very little information. In 1923, Gatenby discussed the question of the formation of new egg-cells in the ovary of vertebrates (NATURE, July 7, vol. 112), and quotes recent work by Allen showing mitoses in the germinal epithelium of Mus (*Amer. Jour. of Anat.*, vol. 31, 5; 1923) as justification for a particular case in which ova may be regarded as being derived from the gonadial epithelium, the so-called somatic part of the ovary. He also gives a photomicrograph of a section of ovary of an adult frog, showing germ-cells in all stages of development, and states "it is indisputable that in vertebrates below the mammals seasonal accessions of new germ-cells take place," without, however, committing himself to views on how this accession occurs. It is admitted that even if mitoses occur in a gonadial epithelium, the interpretation may be made that such dividing cells may be immigrated primitive germ-cells.

In invertebrates germ-cells are found attached to —and apparently proliferating from—the germinal epithelium, and it is generally assumed that such germ-cells have arisen from the underlying epithelium. But the interpretation that mitoses in a germinal epithelium may be due to an immigration of primary germ-cells applies with greater force in the case of invertebrates. It is thus permissible to raise again in a different form the old problem, namely: Which and where are the germ-cells during adolescent and inter-spawning periods? In this inquiry it may not be enough to know the complete ontogeny of a germinal epithelium, unless it be proved at the same time that that germinal epithelium does produce from its own elements—gametes; for it is not impossible that a so-called gonad may be merely the locus in which gametes develop but do not necessarily originate.

On this problem the following observation, which is probably not an isolated case, is of interest. After *O. edulis* has spawned as a female and afterwards as a male (in one and the same summer) the gonoducts fill with leucocytes. My first interpretation of this phenomenon was naturally that the leucocytes were all phagocytes, and employed in cleaning up the gonadial passages ready for next year. No doubt the removal of unused and waste genital products is an important function of these leucocytes, but their abundance has frequently arrested attention and provoked the suggestion that other functions may be being performed. In many cases there would appear to be no necessity for such large numbers merely for phagocytic purposes, although a purely physical explanation may be possible. Is it possible, therefore, that certain leucocytes may be potential germ-cells and only develop such potentialities in a suitable locus, the gonad, at a suitable time? Critical work which aimed at providing definite information on this problem would have great value whatever the result might be. Germ-cells, disguised as leucocytes—and not a few cases of such (as amœbocytes) are indeed known—could be pre-formed in the very earliest stages of development, and be subjected, while in the blood stream, to the maximum net and accumulative effect of the environment on the individual.

That this interpretation is not outside the region of probability may be deduced from Woodger's observations on the origin of the germ-cells of the fowl (*Q. J. M. Sc.*, **69**, p. 460; 1925), and Simkins on Trionyx (*Am. J. Anat*, **6**, 36, 1925). The former states (italics are mine), "I feel no doubt about the continuity of the *primitive germ-cells* of the genital ridge with those of the splanchnic mesoderm of earlier stages, and with the *large cells of the blood-stream* in still earlier ones"; the latter finds that "*Isolated blood-cells* before the origin of the germ-gland rudiment more nearly answer to the requirements of *primordial germ-cells* than any other cells encountered."

The Hoe, Plymouth.

High Frequency Discharges in Gases.

IN the issue of NATURE for Feb. 4, Messrs. Taylor describe a 'new form' of high frequency discharge in gases at low pressures. This type of discharge is one of those which may be obtained when the gas is acted upon by an oscillatory force, derived either from a Tesla transformer where the oscillations are damped or from a generator performing continuous oscillations, and they occur in various forms, many of which are quite well known. The methods of maintaining continuous oscillations at high frequency by means of valves have added additional interest to electrodeless discharges as they provide a means of attaining a steady state of ionisation in the gas so that the currents and the potentials at the electrodes corresponding to the various forms of the discharge may be accurately measured. For this reason they have been included in the experimental courses in Oxford, and doubtless at other universities, and it may be of interest to describe a few of the more striking features which can be made the subject of simple experiments. Luminous discharges in gases may be maintained with long wave oscillations or with oscillations of a few metres wave-length. The resulting phenomena are much the same whether the potentials be applied between external or internal electrodes.

The distribution of the luminosity depends on several factors: the shape of the discharge vessel and the position of the electrodes, which may be internal or external; the nature and pressure of the gas; the applied potential and its frequency. Taking the very general case of a cylindrical tube 1 metre long and 3 cm. in diameter, with two external electrodes wrapped round in the middle of the tube about 10 cm. apart, the following are the main features of the discharge which may be observed as the pressure is reduced. Neon may be taken as an example of a gas which gives brilliant discharges over a large range of pressures from 50 mm to 10^{-3} mm of mercury, using a generator kept in oscillation by a 30-watt valve

At comparatively high pressures the discharge takes place only in the gas nearest the two electrodes. As the pressure is reduced the luminosity extends along the tube until it fills the whole space between the electrodes. With further decrease in pressure the luminous column increases beyond the electrodes, and will finally fill the whole length of a very long tube. Still further decrease in pressure brings a contraction of the length of the luminous column together with a decrease in its intensity. When the pressure of the gas is of the order of 10^{-4} mm. a quite different phenomenon appears. The luminosity breaks up into sharply defined balls of light, sometimes perfect spheres, but in cylindrical tubes usually egg-shaped. Argon shows this phenomenon best, and gives an 'egg formation' with an exceedingly sharp boundary. In general, three balls of luminosity appear: one in the middle between the electrodes and one in each of the spaces beyond the electrodes, but by varying the applied potential it is possible to have one, two, or three 'eggs' existing together or separately.

At pressures of this order it is found that the discharge is maintained much more easily in the vessels of larger volume and in vessels of certain shapes, it is possible to have the discharge entirely outside the electrodes. Further reduction in pressure brings a decrease in the size of the 'egg,' and finally it disappears, leaving a slight diffused illumination from the gas. At very low pressures the glass between the electrodes begins to glow a red colour, and will show a greenish phosphorescence for some seconds after the stopping of the discharge. Quartz will continue to give out a green glow for many minutes after the discharge has stopped. If the quartz be heated above 150° C. it will phosphoresce very brightly for more than an hour, even though the heating be applied many hours after the discharge. Heating to about 600° C. will destroy this power of phosphorescence in quartz. Different types of glass do not seem to phosphoresce on heating.

When a discharge is passed through neon, at 5 mm pressure, which contains mercury vapour as an impurity at a pressure corresponding to the saturation pressure at ordinary temperatures, and the discharge is passed between electrodes round the neck of a tube leading from a large bulb, it is found that the neon spectrum is developed very strongly in the narrow tube with very faint mercury lines, but in the bulb the spectrum is almost exclusively that of mercury. The neon spectrum appears in the strong, the mercury in the weak, part of the field. In general it may be noted that in monatomic gases impurities show themselves in the spectrum to a greater extent in the vessels of large volume where the field is relatively weak and at the higher gas pressures.

Various experimenters have measured the potentials to maintain these discharges under different conditions. One need only mention the researches of Gutton, Kirchner, Gill and Donaldson, and Townsend.

S. P. MCCALLUM.

Electrical Laboratory,
Oxford.

Origin of the Semi-diurnal Pressure Wave in the Earth's Atmosphere.

THE small semi-diurnal wave of atmospheric pressure has long been recognised as a world-wide phenomenon. Simpson (*Q. J. Roy. Met. Soc*, **44**, pp. 1-18; 1918) showed ten years ago how closely its value at individual places corresponds with the resultant of two twelve-hour vibrations, one parallel to the circles of latitude and one parallel to the meridians, as suggested originally by Schmidt (*Meteorologische Zeitschrift*, **7**, p. 182; 1890). The mathematical investigations of Laplace, Kelvin, Margules, and Lamb have led to the conclusion that the atmosphere has a natural period of vibration of about twelve hours. The general opinion during recent years has in consequence been that the semi-diurnal wave of pressure is a forced oscillation of thermal origin, with the reservation that a considerable degree of mystery attaches to the precise way in which such a resonance effect can take place in an atmosphere complicated and changeable as that of the earth. Some meteorologists apparently go even further, and reject this theory completely. Goldie, for example (*Proc. Royal Soc. Edinburgh*, **47**, part 4, No. 25), has been led by a critical examination of many autographic records of meteorological elements, to take up a point of view the essence of which, to quote his own summary, is as follows :

"A semi-diurnal variation appears to some extent in many meteorological phenomena, in particular in barometric pressure, rainfall, visibility, atmospheric electric potential gradient, and atmospheric pollution, even though the variation of temperature, at least in the lower levels of the atmosphere, is very approximately a purely diurnal variation.

"The data examined in this paper suggest that, in the forenoon, insolation affecting the ground and the lower layers, and, in the evening, outgoing radiation affecting clouds and the upper part of the troposphere, each lead to a disturbance of the stability of arrangement of the atmosphere in the vertical direction and to a consequent increased mixing of layers. On the other hand, in the late afternoon and in the later part of the night, as the turbulences arising from the above two effects respectively die down, there is an improvement above normal in the laminarity of flow of atmosphere over the earth. The resultant effect is therefore, on the average, a semi-diurnal variation in the vertical structure and horizontal movement of the atmosphere, which variation is reflected in the meteorological phenomena mentioned above. It is shown in the paper that the various individual effects may be greatly exaggerated, or almost eliminated, or accelerated or retarded, at least in temperate latitudes where a suitable variety of types of upper air structure, from which to select, is available."

It is impossible to deal in detail in a short space with the evidence put forward in support of this view. All this evidence is indirect, and some of it decidedly ambiguous ; it rests mainly upon differences in the character of the diurnal changes of pressure and temperature with different types of weather, and, above all, with different vertical gradients of temperature such as are found on the average in 'polar' and 'equatorial' air that reaches temperate latitudes. No direct observational evidence of a second maximum of convective movement in the troposphere in the late evening is brought forward. Since the diurnal pressure wave is present in clear weather, as well as on days when there are cumulus clouds in the sky to provide foci of radiation, it is evident that the theory relies upon the existence of strong outward radiation from relatively dry air at great heights in accordance with the conclusions arrived at by A. Angstrom (*Q. J. Roy. Met. Soc.*, **50**, pp. 121-125 ; 1924), to which Goldie makes reference. This is a pity, for there are ways of studying upward and downward currents at high levels directly : for example, by observations of the rate of ascent of pilot balloons, or observations of 'bumpiness' made by aeroplane. One would like to know the experience of aeroplane pilots on this point. Simple observation of the collapse of convectional day clouds in the late evening has never suggested to me anything but a gradually increasing tendency to stratification : the last remains of such clouds not infrequently take the form of flattened strato-cumulus, and have never been observed to change into mammato clouds, as might be expected to happen if each cloudlet were descending rapidly towards the earth.

It would appear that, although attempts at the interpretation on dynamical and thermodynamical lines of thermograms and barograms, for selected types of atmospheric structure, may well bring interesting new matter to light, the general conception of a forced oscillation of the atmosphere corresponding with its natural period of twelve hours, as the cause of the twelve-hour pressure wave, will probably continue to hold the field for some time to come

E. V. Newnham.

Rainfall Interception by Plants.

In Nature of Dec. 11, 1926, p. 837, I outlined the results of some observations upon the interception of rainfall by plants. *Inter alia*, it was shown that where an ordinary gauge registered a catch of 1, an adjacent gauge bearing a 12-in. high cylindrical frame of wire-mesh carrying branchlets of *Podocarpus Thunbergii* Hook. registered 1·81 during the period June 1, 1925–May 31, 1926.

Lieut.-Col. Gold, in Nature of Dec. 25, 1926, p. 915, pointed out that the major portion of this interception gain was no doubt due to the frame catching rain which would otherwise have fallen on the lee side of the gauge. He further stated that this would become negligible were a large area to be covered by a comparatively close network of screens.

I accordingly endeavoured to test Col. Gold's statement by means of placing a gauge—screened exactly as described in the note of 1926—at the centre of a close network of concentric circles bearing the laced-in branchlets of Podocarpus. The heights of the circular screens decreased as the centre was approached, and the distances separating the circles were in all instances less than the heights of the latter. A control gauge was placed some yards distant. The catches recorded during the period of observation were :

Month.	Gauge in Centre of Screen Net-Work.	Control.
1927.	Inches	Inches.
April . . .	1·90	1·54
May . . .	12·12	6·77
June . . .	3·37	2·02
July . . .	3·24	2·00
August . . .	6·68	4·16
September . .	4·01	2·63
October . . .	4·40	2·96
November .	3·06	2·44
Total . . .	38·78	24·52
Percentage .	158	100

From observations during periods of rainfall it is obvious to me that, were a closer and more extensive network provided, the seeming interception gain would be reduced still further. I am indebted to Col. Gold for his criticism of the experiment.

The data given in the 1926 note require to be interpreted in light of the information yielded by this second experiment, but at the same time it is certain that the general truth of the argument they purported to support cannot be denied. The following observations at Deepwalls substantiate this claim :

(1) A gauge placed under several 15 ft.-20 ft. high *Virgilia capensis* Lamk., growing on the research station

hill at 1725 ft., registered 0·0025-0·05 in. in six hours during which periods dense *Nebelreissen* cloaked the hilltop, *no actual rainfall occurring the while*. A control gauge placed well away from tall vegetation during these self-same periods registered not the slightest precipitation.

(2) The taller the vegetation the greater the precipitation induced: occasional observations at the base of a row of 100 ft.-115 ft. high *Eucalyptus globulus* growing on the north side of the research station hill indicate that the catch in six hours of dense *Nebelreissen*—without any actual rainfall—may range from 0·0025 to 0·15 in. The writer, while working at the base of these in misty weather, has had to wear a rainproof, so heavy has been the fall of water from the foliage, whereas, when the wind is of low velocity, he has been able to leave papers lying 20-30 yards away from the trees without the records becoming wet. During wind of high velocity it has been noted that an interrupted fall of moisture occurs to a distance of about 40 yards in the direction of the wind.

A continuous series of observations during misty weather has not been possible, but it seems clear that an increased fall of from 10 in. to 15 in per annum occurs under the Eucalpyts as the result of condensation of the hydrometeors. In mountain macchia and mountain forest on the south-west, south, and south-east slopes of the Outeniqua range and of its highest foothills—sites mist-clad on the aggregate a quarter to a half of the year—the increased fall as the result of condensation of the mists must be very much greater.

Active Nitrogen.

IN the current issue of the *Journal of the American Chemical Society*, Dr. Bernard Lewis criticises certain aspects of the work upon active nitrogen which has recently been published from the Laboratory of Physical Chemistry, Cambridge. He states, *inter alia*, that "the authors (Willey and Rideal) neglect to consider many reactions initiated by active nitrogen which require more energy than two volts"; in spite of this somewhat sweeping statement which, if upheld, would stultify a good deal of the work under discussion, he does not quote or even hint at a single reaction which can be held to justify his contention. His next sentence, "The varied phenomena caused by active nitrogen make it evident that 2-volt level nitrogen molecules do not issue from the discharge," is equally illustrative of its author's tendency to state opinions as facts.

It is difficult to understand our being at variance over the obtaining of ammonia from active hydrogen and inert nitrogen. In the experiments at Cambridge, condenser discharges (identical with those employed in obtaining active nitrogen) were employed and careful precautions were taken against mixing of the gases in the discharges. Three concordant experiments showed that ammonia equivalent to about 0·2 per cent. active hydrogen (calculated as H_2) could be obtained if the gases after mixing were further treated with a little water vapour, admitted from another side tube, and drawn to exhaust through a condensing trap cooled by liquid air. In two runs, also, it was found that when the nitrogen was activated no ammonia was obtained, and the glow appeared to diminish slightly, a result which at the time was interpreted as being due to the decomposition by the active nitrogen of ammonia first formed from the inert nitrogen and active hydrogen; the quantity of active nitrogen present (1 per cent.) rendered this quite probable. The experiments were carried out only to test Wendt and Landauer's claims as to the properties of active hydrogen, and were part of the attempts to activate this gas by second-type collisions with active nitrogen as described in the second paper.

It is a pity that Lewis did not make a quantitative study, however short, of his ammonia synthesis from active nitrogen and active hydrogen. Lord Rayleigh has shown (*Proc. Roy. Soc.*, **85**, 219; 1911), and Dr. Rideal and the author have confirmed his observation, that ammonia extinguishes the glow of active nitrogen and chemical reaction appears to be traceable. This fact would appear to constitute a grave objection to Lewis's theory of the formation of ammonia from atomic nitrogen and atomic hydrogen, namely:

$$N + H \longrightarrow NH \quad . \quad . \quad . \quad (1)$$

$$NH + H_2 \longrightarrow NH_3 \quad . \quad . \quad . \quad (2)$$

Spectroscopic evidence, taken in conjunction with the decay of the afterglow being bimolecular with respect to the glow-producing system, leads to the view that the first step at any rate in the development of the luminosity is the recombination of nitrogen atoms, which are the primary reacting system according to his scheme. If, then, they are to take part in the ammonia synthesis, considerable changes—probably extinction—of the glow might be anticipated; conversely, if ammonia were produced in any quantity by any other mechanism, it should also affect the glow, but no mention of such a phenomenon occurs in his paper. The matter will later be discussed more fully in another place.

Recent studies of the decay of the after-glow have, it is believed, led to important clues as to the origin and nature of active nitrogen. It appears that between 1 mm. and 10 mm. pressure the decay process is very complex, although bimolecular with respect to the active nitrogen. Moreover, it appears very likely that the luminosity and the chemical activity are steps in an involved deactivation process; the first of these stages appears to consist of a ternary collision between two atoms and a molecule, as would be expected from the negative temperature coefficient of the decay process as observed long ago by Lord Rayleigh (*Proc. Roy. Soc.*, A, **86**, 262; 1912).

A full account of these investigations will shortly be published.

Units of Energy.

DR. RUSSELL'S suggestion (NATURE, Feb. 4, p. 170) that the kilowatt-hour is the best unit of energy for practical purposes, ought to be popular with the gas companies. At present, by Act of Parliament, we have to purchase our energy from the public supply companies by two different measures, and the cheaper purveyor does not get full credit for his cheapness. The unit for electricity is of course the kilowatt-hour, $3{\cdot}6 \times 10^6$ joules; the unit for gas energy is the therm—the energy required to heat 1000 lb. of water through 100° F., and this is 105×10^6 joules. Thus the therm is approximately 29 kilowatt-hours. In other words, when the price of gas per therm is the same as the price of electricity per kilowatt-hour, electrical energy is 29 times as dear as gas energy.

As to the scientific aspect of the question of units, it would be useful if someone with missionary zeal could provide handy reference tables bringing in all the different forms of energy. The subjoined list gives some indication of what is wanted, and suggests to my mind the reflection that it would not be beneficial to adopt one unit of energy to the exclusion of the others.

For the benefit of meteorologists who are interested in the measurement of geopotential, I have included in the table the unit introduced by Prof. V. Bjerknes, the dynamic metre or, as I prefer to call it, the metre-leo. This is the gain in potential when a body is raised through 1 metre in a hypothetical place where $g = 1000$ cm./sec.^{2}. The metre-leo is 10^5 ergs per gramme. The specification of the upper levels of the atmosphere by geopotential rather than by height has certain theoretical advantages, the principal one being that points with the same geopotential are on the same level surface. Whether it is desirable to use the metre-leo in recording observations is a question on which opinion is at present sharply divided. The question has been answered in the affirmative by more than one international conference, but some of the most influential meteorologists hold strongly the contrary view. My little table, in which the simple relation between the second and third columns will be noted, may serve to show why the proposal has some attractions for students of dynamical meteorology.

Density of a Luminous Gas and the Emission of Light by Atoms in Metastable States.

Mr. I. S. Bowen points out in an interesting letter to Nature (Oct. 1, 1927, p. 473) that the low density prevailing in nebulæ favours the emission of light by atoms in metastable states, and thus he accounts for a number of hitherto unexplained nebular lines as the result of transitions from initial metastable states of ionised atoms of oxygen and nitrogen. There is no doubt, as Prof. Fowler, who has adduced further spectroscopic evidence in support of the suggestion, puts it, that "a satisfactory explanation of some of the most important nebular lines has at last been reached." The suggestion, however, implies that we have to give up the position that the transition of an atom from a metastable state to one of lower energy level resulting in emission is necessarily conditioned by the action on the atom of an agent external to it, an electric field, a magnetic field, or the impact of another atom. If, as is sometimes alleged, the influence of neighbouring atoms causes the emission of forbidden lines from initial metastable states, a high density, and not a low one, should be the condition favourable for such emission.

It has been shown by me that the intensity of the forbidden line λ2270 in the arc spectrum of mercury resulting in the transition from the initial metastable state 2^3P_2 to the ground level 1^1S_0 *increases* as the density of the vapour in a mercury arc is *diminished*, other conditions of excitation remaining unaltered (*Roy. Soc. Proc.*, A, vol. 117, p. 20, communicated July 7, 1927). Quoting from the paper, "these considerations would appear to indicate that the metastable state 2^3P_2 is not one in which, left to itself, the excited atom remains for ever in that state, but one whose average free life is large compared with the average life of other excited atoms . . . the (free) life of an excited atom in the metastable state is so long that in an arc under a pressure of the order of a couple of millimetres of Hg the probability of such an atom suffering during its life an inelastic impact resulting in a radiationless transition approaches certainty." It appears to me that the behaviour of the mercury line λ2270 described in the paper referred to above is of the nature of a crucial experimental confirmation of Bowen's brilliant suggestion.

The Constituents of Low Temperature Tar.

In Nature of Dec. 4, 1926, p. 805, which has only recently come to my knowledge, I find a notice by Messrs. G. T. Morgan and D. D. Pratt which interests me greatly, because it contains a confirmation of an observation which I made and published some years ago (*Berichte der Deutschen Chemischen Gesellschaft*, 39, 1238; 1906). It concerns the occurrence of β-methylanthracene in low temperature tars from certain coals. I have already demonstrated this for three poor ('magere') coals, that is, geologically old Westphalian coals, with a coke content of 82 per cent.—at the same time the yellow hydrocarbon, crackene, was isolated—and it may well be supposed that the coal employed by Messrs. Morgan and Pratt displays a similar character. That β-methylanthracene is indeed concerned, I have already proved in a similar manner to Morgan and Pratt by the oxidation product of the hydrocarbon. More recently I have arrived at this proof by another way (*Berichte der Deutschen Chemischen Gesellschaft*, 59, 2812; 1926),[1] which, however, leads to the same result, namely, the preparation of a double compound of the hydrocarbon with β-dinitroanthraquinone (Fritzsche's Reagent).

E. BÖRNSTEIN.

Berlin-Charlottenburg.

BY the courtesy of the Editor of NATURE we have seen the foregoing letter from Prof. Börnstein, in which he states that our letter to NATURE of Dec. 4, 1926, confirms an earlier observation of his as to the presence of β-methylanthracene in low temperature tars from certain Westphalian coals (*Berichte der Deutschen Chemischen Gesellschaft*, 39, 1238; 1906). In a later communication (*ibid.*, 59, 2812; 1926) Bornstein, Schliewiensky, and Szczesny-Heyl had expressed a contrary opinion, but Prof. Bornstein's footnote now indicates that this discrepancy was due to a typographical error. With this correction his two observations are now in agreement with ours.

We would take this opportunity of stating that investigations on the aromatic hydrocarbons of low temperature tar are still in progress in this laboratory. Other anthracene derivatives have been isolated in considerable quantities, together with complex hydrocarbons including the so-called 'crackene.' Further details of these researches will be published in the near future.

Activation of Hydrogen by Electric Discharge.

IN Dr. Elliott's absence, en route to Australia, I venture to indicate certain difficulties inherent in the hypothesis proposed by Mr. G. Glockler in NATURE of Jan. 21 for the mechanism of the formation of hydrogen sulphide in experiments on active hydrogen produced in an ozoniser discharge. At a constant alternating potential applied to the ozoniser electrodes, and at a constant gas pressure, it is clear that, as the velocity of gas flow is increased, the number of electrons per litre of hydrogen available for adsorption on the sulphur is increased since the interval in which recombination can take place is diminished. Dr. Elliott's experiments show that under such conditions the amount of hydrogen sulphide formed per litre of hydrogen decreases as the velocity of gas flow is increased.

It is to be anticipated that the passage of the gas through glass wool would greatly diminish any residual ionisation, due to surface adsorption and recombination. The rate of formation of hydrogen sulphide remains, however, unchanged when the glass wool is removed. ("Action of the Corona Discharge on Gases", G. A. Elliott, Thesis, University of London, 1927.) If a stray field capable of sustaining ionisation had existed in the neighbourhood of the sulphur, any reaction due to electrons adsorbed on the sulphur would also increase with increasing gas flow, since a greater mass of ionised gas would then come in contact with the sulphur in unit time.

At the lowest pressures investigated the luminous discharge did extend to the sulphur; the intensity of this stray glow could be greatly increased by attaching an earthed wire to the tubing below the sulphur. No change in the amount of hydrogen sulphide formed was obtained by this procedure: it appears that the hydrogen capable of reacting with sulphur is produced in the principal discharge in the ozoniser only. The suggestion that the formation of hydrogen sulphide results from encounters between simple positive hydrogen ions (H_2^+, H^+) and negatively charged sulphur cannot, therefore, be accepted.

Movements of the Lower Jaw of Cattle during Mastication.

STIMULATED by the interesting communication of Dr. Jordan and Mr. Kronig (NATURE, Dec. 3, 1927) concerning the direction of rotation of the jaws of cows in North Sjælland during mastication, we have ourselves carried out similar investigations. We have made the interesting observation that the direction of rotation is the same whether the cow be taking in food through the mouth or ruminating. If according to the convention of the above-mentioned authors we choose as the positive direction that of the food, it follows that one and the same cow must be classed sometimes as right-handed and at others as left-handed. If we may assume that the processes of taking in food by the mouth and of rumination alternate, then it follows that the cases of right-handed and left-handed mastication must of necessity be equal in number. The fact that the former investigators did not find a ratio of exactly one to one is then presumably due to their not having made equal numbers of observations on the two different phenomena.

The Spark Spectrum of Neon.

BY the use of a vacuum spectrograph, in which the spectrum was excited by electron impacts at controlled voltages between a Wehnelt cathode and a wire grid anode, we have discovered a new series of lines of considerably shorter wave-length than any hitherto reported for neon. There are 15 of these lines between wave-lengths 462·38 and 353·01. They show the wave number difference 782 expected of the neon spark spectrum, and have in fact led to an almost complete analysis of the spark spectrum, in which 203 lines have been classified in 59 multiplets. From this analysis the ionisation potential of the neon ion is found to be 40·9 ± 0·05 volts.

Marcello Malpighi.

(1628–1694.)

THE three-hundredth anniversary of the birth of Marcello Malpighi, the Italian whom Sir Michael Foster designated "anatomist, physiologist, botanist, pathologist, biologist, and above all natural philosopher," occurs on Mar. 10.

Born at Crevalcore, a village near Bologna, Malpighi was one of the sons of a small farmer. Proceeding to the University of Bologna, he engaged in medical studies, graduating there in 1653, after four years' work, with a doctor's degree. Three years later he transferred to the University of Pisa, taking up the professorship of medicine; here he formed a friendship with Borelli, the mathematician, who encouraged him to pursue researches in anatomy. In 1662, Malpighi removed to Messina to occupy the chair of medicine, remaining there four years. Always subject to insecure health, a request to return to Bologna was willingly obeyed, and there Malpighi spent twenty-five years, fruitful in results. Summoned to Rome in 1691 as first physician to Pope Innocent XII., he died in that city three years later whilst holding office. Such is the summary of his ordinary life avocations.

In reality, however, we must extend these boundaries and regard Malpighi as a philosophic naturalist, a pioneer investigator, and a founder of microscopic anatomy. He had constant resort to the microscope, observing with its aid the passage of blood cells from arteries to veins. He made discoveries relating to the structure of the kidneys and spleen. He also investigated vegetable structure. If not endowed with a subtle instinct—it has been said that his physiology was necessarily of the unspecialised kind—he was yet competent to make general conclusions, fully endorsed afterwards.

We may appropriately allude here to Malpighi's connexion with the Royal Society of London in its earliest days, and with contemporaries such as Boyle, Hooke, Oldenburg, and Grew. Oldenburg, ever anxious to foster relations with foreign investigators, was doubtless first in the field to invite correspondence from Bologna. It seems to have begun in 1667. In the following year Malpighi wrote to Gresham College, sending a book, and expressing readiness to communicate "philosophical matters." A bond was henceforth established with the Society which almost obliterated nationality, actuated as it was by a true spirit of fraternity.

At this time, moreover, there was much Italian sympathy for science, of the kind, that is, that existed. It is recorded that at the very next meeting after Malpighi's letter was received, two Italian gentlemen were present, introduced by Count Ubaldino. They acquainted the Society of the singular respect which the Cardinal Leopold de Medicis had for them, and that he desired to have his excuse made for not having himself returned his acknowledgments for the History of the Society sent to him, which he had been hindered from doing by his lately acquired dignity of Cardinal; but that since that time he had desired and already obtained the Pope's permission to correspond with the Society, of which he now intended to make use to let them see the esteem which he had of them and their institution. Whereupon the president thanked these gentlemen for acquainting the Society with so favourable an inclination of his Eminence to them, and that they would study to entertain so noble and promising a correspondence with all reciprocal services that might be acceptable to his Eminence.

At a meeting of the Society held on Feb. 18, 1668/9, "Mr. Oldenburg brought in a packet sent to him by Signor Malpighi containing a manuscript history of the silk-worm, its whole life, and the anatomy of all the parts thereof, consisting of twelve folio sheets with as many microscopic draughts in folio. It was ordered that the hearty thanks of the Society be returned to the author by a letter to be drawn up by Mr. Oldenburg; and that he and Mr. Hooke be desired to peruse those papers, and to make a report thereof . . . and that the consideration of publishing them be referred to the council." As is well known, the decision was taken to print the treatise, "De Bombyce," and Lord Brouncker, the president, communicated the order to Malpighi. Hooke had found it "very curious and elaborate, *well worth printing*."

On Mar. 4, 1668/9, Marcello Malpighi was proposed by Oldenburg as an honorary member, and elected *nemine contradicente*. Oldenburg was directed to draw up a special diploma. It is scarcely necessary to say—the fact is generally known—that Malpighi never attended any meeting at Gresham College, and hence the Charter Book does not bear his signature.

A letter to Oldenburg, presented on Mar. 23, 1670/1, contained "several curious remarks on the communication between the bronchiæ and lungs in frogs, lizards, and tortoises." On Dec. 7, 1671, a manuscript was produced, sent by Malpighi, containing an abstract of his observations and considerations of the structure of plants. It was ordered that he be solemnly thanked "for his singular regard for the Society and his great care of improving natural knowledge: as also that it be signified to him that Dr. Grew had made the like attempt in his 'Anatomy of Vegetables,' lately published in English; and that the Society would be very glad to see Signor Malpighi's labours on that subject brought to that perfection which was intended by him." In the spring of 1680 the Society sent to Bologna some small microscope glasses (by Mellin) as a present. Later on, Hooke announced the welcome gift from Malpighi of his portrait "very well painted, as big as the life." A letter full of tribulation was received from him in 1684 mentioning the burning of his house, whereby he had lost all his *adversaria* and microscopes.

Malpighi's autobiography, and collections of many important contributions to the anatomy of plants and discoveries in physiology, were published in London in 1696, under the auspices of the Royal Society. In 1897, Malpighi's native town, Crevalcore, marked the bicentenary of his death (1894) by a festival of homage, when a bronze statue of the philosopher, erected in the market place, was unveiled. A memorial volume was issued afterwards, containing appreciations by Virchow, Weiss, Haeckel, Kölliker, and others.

This brief notice, written for remembrance' sake, may fitly close, as it began, with words written long ago in this journal by Sir Michael Foster—"To look across two centuries at a great man, struggling with the beginnings of problems which have since come down to us, some in part solved, but others with their solutions put still further off by the very increase of knowledge, is a useful lesson to every one of us. In any case the great men who in the past opened up for us paths of inquiry . . . ought not to remain mere names known to us chiefly through being attached to some structure or to some piece of apparatus. We ought all of us to be able to form some idea of what they were and what they thought." T. E. JAMES.

Geophysical Prospecting.

By Prof. A. S. EVE, F.R.S., McGill University, Montreal.

> "Here we are on Tom Tiddler's ground
> Picking up gold and silver."
> —*Song of an Old Game.*

AN eminent geologist has said that "the best way to find out what is under the ground is to bore a hole in it." Truly the diamond drill is the miner's best friend in exploration, presenting samples of successive layers for him to worry over with the geologist; but drilling is an expensive game and the world is wide, so that some guidance is necessary as to where to bore the next hole.

Until quite recently the chief aids to exploration were (1) the divining rod, known in the U.S.A. as the 'doodle bug,' not now used by any mining engineer of repute; (2) magnetic surveys, whereby can be found magnetic ores, such as magnetite or pyrrhotite, but ineffective for non-magnetic ores such as pyrites; and (3) the intelligent applications of geological principles.

To-day, however, there is much more assistance available, new in type, and varied in character. Just as invisible and submerged submarine boats may be detected from the surface of the sea by some physical dissimilarity between the boat and its surrounding medium of sea water, so also ore bodies of fair magnitude can be detected by the wise appreciation of some inherent property different in the ore from the surrounding medium of rocks. Oil has not yet been detected by direct methods; the search has been rather for folds below the ground or for salt domes, where the oil tends to collect in paying quantities.

Now the chief methods of ore hunting, which is a good sport, are these: (1) Electrochemical detection; (2) electrical, tracing the equipotential lines between earthed conductors using direct or alternating current; (3) magnetic methods, as heretofore; (4) electromagnetic detection with direction-finding coils, not unlike direction-finding by ships at sea, only here the ore body must be stimulated by alternating currents flowing in horizontal or vertical loops, using audio or radio frequency. This is the hunt for an electrical echo.

In the search for oil the procedure is usually quite different, and this fact is evidence of the great flexibility of geophysical operations in the field. The chief methods for oil hunting are: (1) Seismic, using an artificial explosion and a seismograph a few miles away to detect the first swift message of the uproar, travelling by a route far down below the earth's surface; (2) gravitational, using that most exquisite and sensitive apparatus, an Eötvös torsion balance; (3) magnetic, where disseminated magnetite makes such search possible; (4) electrical, just as for ore bodies, but on a larger scale. So far, no certain information as to the success of this last method over oil fields is available.

Many of these methods have been already well tested over 'proving grounds' above known ore bodies, so that to some extent their rival merits are known to the initiated, while on the other hand many mine managers and engineers are puzzled to distinguish between those schemes which rest on a sound scientific basis, and other plans which may be termed psychological, fraudulent or subconscious methods, based on the mystical or unknown, sometimes worthy of study, but with a balanced scepticism.

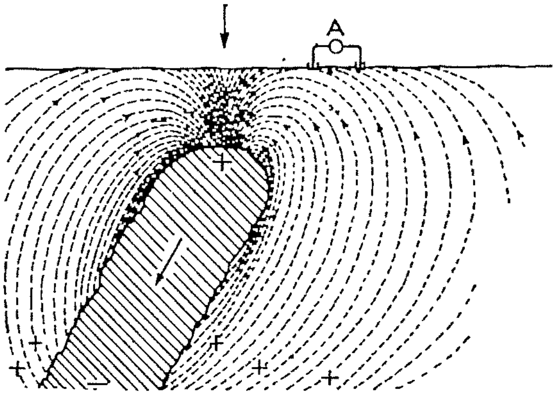

FIG. 1.—Diagram illustrating a sulphide ore body acting as a battery while being oxidised above by rain and surface water. Current lines are dotted and the galvanometer and two detecting electrodes are shown at *A*

Sulphide ore bodies are slowly oxidised by surface and rain water, so that the mass acts as a large battery with the negative electrode the higher, so that currents flow towards this upper region from below (Fig. 1). The current can be readily detected by non-polarisable electrodes placed on the ground and connected by insulated wires to a sensitive galvanometer or portable microammeter. This method was first due to Barus, and it has been extended by Schlumberger, using porous pots containing a saturated solution of copper sulphate and a copper rod as electrode. All sulphide bodies which oxidise, and also magnetite, may be detected by this simple and direct process. The depth of detection must naturally depend upon the size of the ore, the rate of oxidation, and the conductivity of the ground around and above it.

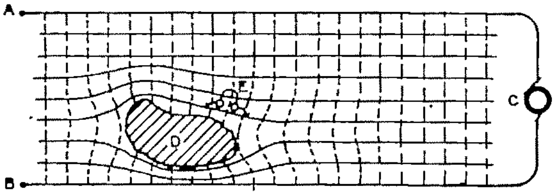

Fig. 2—Diagram of an alternating current sent from generator *C* to two long bare copper conductors well connected to the earth The lines of current flow are normally perpendicular to the conductors, but tend to crowd toward the good-conducting ore body *D*. *E* is the telephone (with amplifier) for getting silence points on the equipotentials which spread away from the ore body.

As to direct electric methods, it is safe to commend the long parallel bare copper wires pegged to the ground to which the current from a dynamo or a few ‘B’ batteries is led. Detection may be made, with due allowance for the natural or electrochemical currents, by the same electrodes and microammeter as those just described. Lundberg, to whom this parallel conductor scheme is due, uses about 500-cycle alternating current in the parallel conductors, and obtains his equipotentials with the help of iron electrodes thrust into the ground, whence insulated wires lead to a telephone headpiece, with such amplification as may be desirable. Since lines of current-flow converge into good conducting ore bodies, it follows that equipotentials tend to curve away from and around the ore body, both underground and on the earth's surface (Fig. 2). It is naturally impossible to detect by such methods those ores like zinc blende, the conductivity of which is almost identical with that of the surrounding rock. Nor is it possible to declare whether the indication is due to a worthless or to a paying vein.

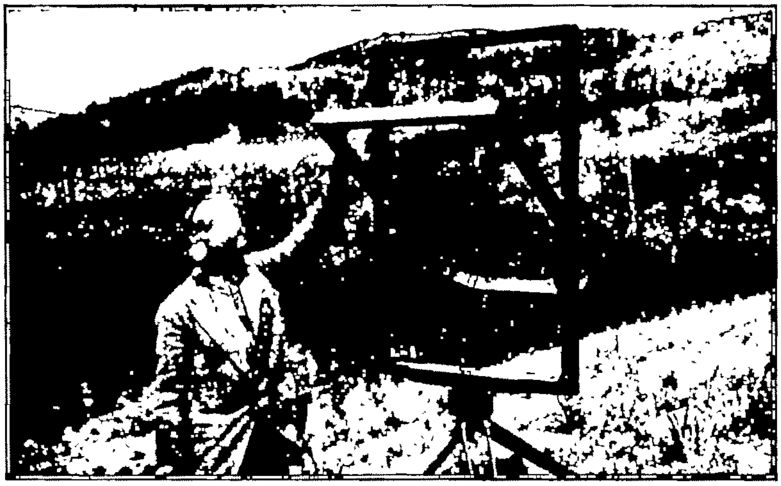

Fig. 3.—Transit tripod with coil, turning in azimuth or dip, and the telephones Large horizontal loop with 500-cycle alternating current Near Caribou Mine, Colorado.

Instead of two parallel wires, a large loop of well-insulated wire may be laid upon the surface of the earth and an alternating current from a 500-cycle generator passed around the loop. This current will cause an electromotive force and resulting current around the ore body. A coil near the surface of the earth will be stimulated by induction, and again detection can be made by head telephones and amplifier (Fig. 3). Direction, magnitude, and phase of this induced current can all be investigated, and the scientific problem is one of some complexity and great interest. Lundberg and Bieler, for example, use detection methods which are quite different in actuality though apparently the same to a superficial observer. One compares magnitude, the other, balancing phase difference, compares horizontal components with the vertical.

The Radiore Company uses a vertical loop of many turns to which is led alternating current of high or radio frequency (10,000 metres wave-length). The ore body is stimulated by induction rather than by radiation, and the effect is again detected by a loop, tuned to resonance, with amplifier and head telephones. The penetration to some depth into the earth and the emergence from that depth of the excited radiation presents some interesting and important physical problems awaiting further investigation. Dr. Appleton suggested to the writer the possibility of producing repeated maxima and minima in the coil by gradual change of wave-length in the loop, so that a vein or sheet of conducting ore body might have its depth determined by a method quite analogous to that by which he has found the height of the Heaviside layer far over our heads, which renders radio telegraphy or telephony effective by reflection and refraction. The difficulty arises, however, that in ore-prospecting short radio waves must then be used, and such waves do not travel far into the earth.

Investigations of these and allied problems over a known ore body or ‘proving ground’ may well fall within the scope of government-assisted research. Thus, last summer the United States Bureau of Mines had a party working near the Caribou Mine, 10,000 feet up in the Central Rockies in Colorado. This party consisted of Dr. C. A. Heiland, of the School of Mines, Boulder, Colorado; Dr. D. A. Keys, of McGill University; and the present writer. Satisfactory and concordant results were obtained with magnetic and diverse electrical methods, and a new scheme was also evolved which was quite effective in the dry region of the Rockies, but disappointing amid swampy districts when tested in Northern Quebec. Indeed methods must be varied to suit local conditions, and all eggs in one basket is a poor policy. The reports of this expedition will be published this year by the Bureau of Mines, Washington, following a brief summary, already published, of the elementary principles involved (Technical Paper 420).

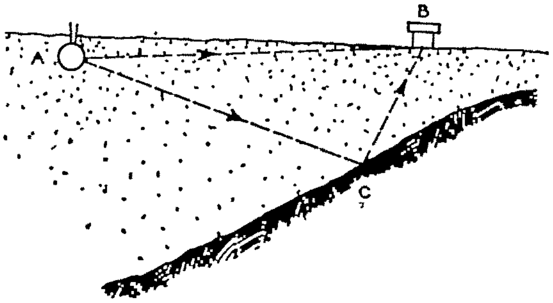

FIG. 4.—Diagram showing small charge at *A* sending out waves which are reflected upward from a fault or discontinuity at *C* and pass to *B*, so that the route by way of the fault (*ACB*) may be quicker than direct route *AB*, because speed increases with elasticity and therefore with depth. All the lines should be drawn slightly curved, concave upward.

Extensive experiments both in the laboratory and in the field have been made during the last four years by Dr. Max Mason, president of the University of Chicago. His interesting address to the Mining and Metallurgical Engineers of America has been printed, and can be obtained from the Physical Exploration Corporation, 111 Broadway, New York City. This is a valuable report which indicates the scope and possibilities of geophysical methods.

Let us revert to oil hunting. The sound work done in south-west Persia with the Eötvös torsion balance has been set forth clearly in Appendix 12 of the "Summary of Progress of the Geological Survey of Great Britain for 1926" (London: H.M. Stationery Office). In Texas and Mexico, although abundant work has been carried out by the great oil companies of America, yet all this information, whether obtained by gravitational or seismic methods, at great cost to these companies, is retained as confidential, and they do not publish the methods employed or the results obtained.

The Eötvös balance consists of two small heavy gold balls at the ends of a light aluminium bar suspended by a platino-iridium wire. If the balls were at the same level and if the earth were a uniform sphere at rest, the arrangement would be astatic. Actually, however, such a torsion balance, truly of the Henry Cavendish type, tends to set itself along the direction of maximum or minimum curvature of the irregular level or equipotential surface at the place under investigation, and we can find $g(1/R_1 - 1/R_2)$, the horizontal direction tendency (H.D.T.) in magnitude and direction. R_1 and R_2 are the minimum and maximum radii of curvature of the 'level' surface. The torque tends to set the beam along the ridge of an anticline and across the valley of a syncline. Eötvös, however, hung one ball about sixty centimetres below the other and thus determined also the direction and magnitude of the gradient of gravitation, which is the change of numerical value of g per horizontal unit distance. The vertical gradient of gravity does not here concern us at all. The theory of the torsion balance is often obscured by double partial differentials which alarm the unaccustomed reader, whereas the problem is one of ordinary statics with a slight admixture of dynamics and three-dimensional analytical geometry. The truly alarming feature of the work is the correction for altitude and latitude and for terrain and topographical features. In many cases, however, comparative values of the H.D.T. and of the horizontal gradient of gravity are all that are required for the determination of some local problems in geology or mining.

In seismic work, small charges of high explosives are used to obtain reflection of the shock from faults or discontinuous strata. In these cases the time to the seismograph by the direct route is comparable to the time by the reflected route, and the record is therefore hard to interpret (Fig. 4). It will be noted that this plan resembles quite closely the methods now available of determining the depth of the ocean by echo methods. Much larger scale work is used in the Gulf region. There large charges of 150 lb. of T.N.T. are exploded and timed by radio signal. The velocity of the shock is governed by the elasticity and by the density of the medium. Density varies but little with depth, but the elasticity increases with the pressure, and the pressure with the depth, perhaps in a linear relation. Hence the first shock signal which travels a few miles and reaches the recording seismograph is that compressional wave which has passed deep down a few thousand feet into the earth and emerged after its curved and concave path (Fig. 5). If a salt dome intervenes, there is yet higher speed, and by numerous shocks and measurements the size and shape of the salt dome may be determined; the site purchased,

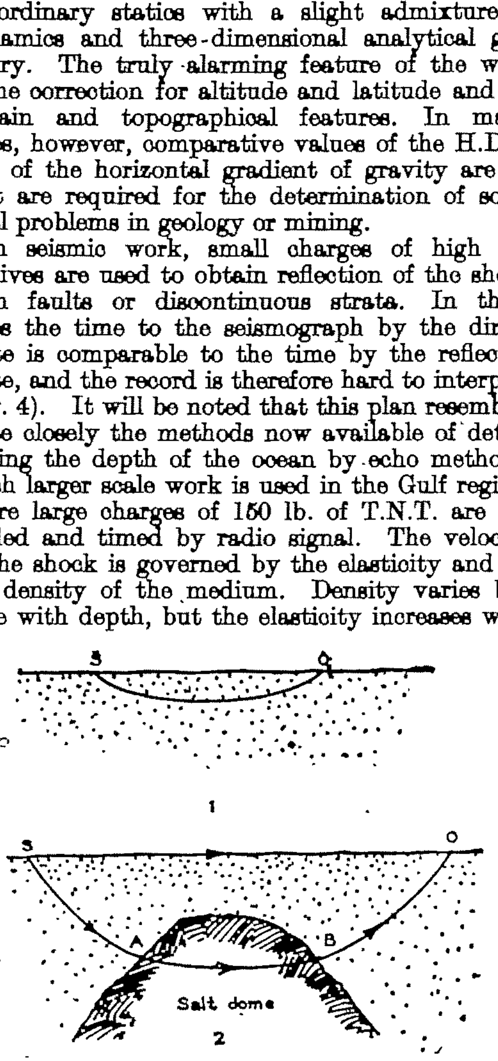

FIG. 5.—Diagram showing (1) that the quickest path from an explosion at *S* to an observer at *O* is a curved one, *SO* (diagram 1), through the earth, because elasticity increases with depth, and (2) that *S* and *O* are farthest apart and the quickest route *SABO* (diagram 2) is by way of the salt dome beneath, which can be thus detected because of the high velocity of the waves in the salt dome.

and the hunt for oil, now aided by torsion balance work, pursued. If success follows, there is avoided that scramble for the oil field which has so often in the past involved loss due to hasty and wasteful boring and pumping, and violent fluctuations in supply and cost.

To sum up: geophysical methods wisely used can be helpful and profitable. If the possibilities are over-stated or improper claims made, there will be a lack of confidence retarding that advancement which careful development should achieve.

News and Views.

The discovery in the United States in 1922 by T. Midgley that lead tetra ethyl has a remarkable action in delaying detonation or 'knocking' in the internal combustion engine when added to petrol in minute amounts, has brought this organo-metallic derivative from the obscurity in which it had remained since it was first prepared and described in Great Britain by Buckton nearly seventy years ago (*Phil. Trans.*, **149**, 431) to be an important article of commerce. It is an oily colourless liquid, density 1·66; of boiling point above 200° C., with decomposition. It possesses toxic properties which are specific in character and differ from ordinary lead poisoning in that the first symptoms are insomnia and fall in blood pressure. The oil is slightly volatile and can be absorbed through the skin. Attention has been directed recently by eminent chemists to these poison dangers which might occur with the indiscriminate use of petrol containing small amounts of lead tetra ethyl, and on Feb. 29 in the House of Lords it was announced that an Interdepartmental Committee is to be appointed forthwith consisting of representatives of the Ministry of Health, the Home Office, and the Medical Research Council, to investigate the poison hazard associated with the sale of ethyl petrol in Great Britain.

In 1924, at an experimental plant in New Jersey, where the manufacture of pure lead tetra ethyl was being carried out, a number of serious poison cases occurred, and the newspaper publicity which followed led to a voluntary suspension of the sale of ethyl petrol in the United States until the poison hazard had been investigated by the Surgeon-General of the U.S. Public Health Service. It was recognised that the manufacture and handling of lead tetra ethyl is attended with danger if not done with proper precautions, but the debatable points were the hazards to retail distributers, garage employees, and the individual users of ethyl petrol in which the lead compound is diluted by about one part in 1300. After elaborate and careful investigations, it was concluded by the Surgeon-General that no poison hazard could be traced to the use of ethyl petrol, and the manufacture of lead tetra ethyl was resumed on June 1, 1926. Researches in the direction of finding other substances of a non-poisonous character and equally as efficacious as lead tetra ethyl, have up to the present been without success, although iron carbonyl is used to some extent in Germany, so that unless a grave and well-established hazard exists, the abandonment of the use of lead tetra ethyl does not appear to be justified.

It is, perhaps, little appreciated in Great Britain that the present low price of sugar has placed British Colonies which supply us with this commodity in a distinctly precarious position; and it is not generally recognised how vital a matter Imperial preference is to some of the British West Indies, Mauritius, Demerara, and Fiji. There are two main factors concerned, one economic and one scientific; and the latter is the general low level of research work in our cane plantations. The almost universal aim in progressive cane-sugar countries is to induce the plant to produce more tons of sugar to the acre; for this purpose men versed in scientific methods have been enlisted. It must be confessed, however, that the British Colonies are very much behindhand in this respect. A short article in the current issue of the *International Sugar Journal*, under the heading "Scientific Work in the Plantations," deals with this matter, using as a text the action of the Oahu Plantation Company in the Hawaiian Islands, when faced with the serious situation caused by the trade slump following the boom year of 1920. In January 1921 this company founded a "Department of Agricultural Research and Control," and the results thus far obtained by its scientific officers on one single programme of work, namely, the proper feeding of the cane with artificials, are briefly summarised. Astonishing success has attended the application of scientific research to the fields for this purpose; and it is claimed that if in the factory a piece of machinery were invented giving equal financial results, it could be capitalised at one million dollars. So it would seem that such an investment in research is a paying proposition.

The quarterly report of the Empire Cotton Growing Corporation, issued on Feb. 9, clearly indicates the extent to which this body is involved in the present serious crisis in the Lancashire cotton industry. The purpose of the Corporation was described and discussed in our issue of Nov. 5, p. 645. Briefly, its income is, in the main, obtained from a levy of 6*d.* per bale of cotton entering England; and its aim is to enable British buyers to control this raw material, by increasing the amount grown within the Empire. The Act legalising the levy expires in July next, and representative bodies have been sounded as to the attitude likely to be taken up by the trade when the question comes before Parliament during the present session. The result of this inquiry appears to be that, while fully appreciating the work that the Corporation has been able to accomplish, it is unlikely that the spinners will agree to the continuance of the levy, at any rate at the present figure.

The position of the cotton industry has, indeed, become so precarious that drastic retrenchment in every possible direction has become a vital necessity, and, as is so often the case, the reduction of research is considered a possible economy. The only hope is that the industry will consent to a reduced levy. If this is denied, the Corporation may have to close down—a contingency not only adverse to Lancashire, but also to most of the cotton growing dependencies of Great Britain. Lord Derby, in presenting the report of the executive committee, directed attention to some of the progress which has recently been made, and issued a powerful appeal to the Lancashire cotton trade to support the fresh Bill about to be introduced. The work of the Corporation is both economic and scientific; and one instance of marked scientific success is the result of plant-breeding work, which has cleared away the main hindrance to cotton growing in the important cotton tract of the Union of South Africa.

THE committee appointed on Jan. 16 by the conference of Thames riverside authorities in connexion with the floods in the London area of Jan. 6–7, presented on Feb 29 a unanimous and authoritative report. A technical sub-committee, which examined the hydrographic, meteorological, and hydraulic questions involved, reported that on the information at present available, more could not be said in explanation of the tide of Jan. 6–7 than that it was due to a combination of a spring tide, not in itself exceptionable, the raising of the water in the estuary by the meteorological conditions of the North Sea, and by flood waters from the upper Thames. On the question of future probabilities, it was reported that the whole subject of tides in the Thames requires further expert investigation, and it is recommended that this investigation should be undertaken by the Tidal Institute of the University of Liverpool, in co-operation with the Hydrographic Department of the Admiralty and the Meteorological Office. A scheme of warnings of the possibility of storm-floods was drawn up and recommended by the committee, subject to any improvements which the report of the special investigation on tides may suggest. The main points of this scheme are the following: (1) Public announcement to be made by the Meteorological Office, after consultation with the Port of London Authority, should climatic and tidal conditions be such that exceptionally high tides may be expected. This is an initial precaution. (2) Special watch to be kept at Southend, and, should the tide reach a specified high point, warning to be given to the appropriate authorities. (3) Watch then to be kept at selected points, and public warning to be given in the locality if the water reaches danger level, the London County Council to specify the danger level at each point and the locality to be warned.

MUCH interesting historical information on exceptional high waters in the Thames is set out in the Committee's report, and it is concluded that on the basis of records alone, there was no reason to expect a tide of the magnitude of that of Jan. 6–7. So exceptional was this recent storm-flood that its high water was eleven inches above the highest previously recorded, namely, that of Jan. 18, 1881. The Committee shows that whereas during the last thirty years the yearly average height of high waters at Crossness, on the seawards border of London, has remained steady, the corresponding average at Hammersmith has shown a small but continuous upward trend. The phenomenon at Hammersmith is probably to be attributed to the dredging and other changes which have been made in the bed and sides of the river, but the Committee quite properly points out that what is important for flood-works is not average high-water levels, but what may be expected in the way of exceptionally high tides.

LITTLE progress appears to have been made as yet in the discovery of principles which will enable storm-floods to be forecast from a knowledge of meteorological conditions. From noon until midnight on Jan. 6, there was a north-westerly gale over the North Sea and a westerly gale over the English Channel. On the other hand, the flood of Jan. 18, 1881, was preceded by a south-easterly gale which changed to easterly and then to north-easterly. The floods which occurred on the eastern shores of the North Sea in January 1916 have been studied by L. Grossmann, of the Deutsche Seewarte, and by D. la Cour, of the Danske Meteorologiske Institut. Those which occurred on the coast of Flanders during the German occupancy have been studied by Bruno Schulz, of the Deutsche Seewarte. More progress has been made in correlating with meteorological conditions those much smaller but fairly steady changes in sea-level which are almost invariably present in addition to the regular tides. In recent years important contributions to this subject have been made by R. Witting of the Helsinfors Havsforskningsinstitut for the Baltic and by A. T. Doodson of the Liverpool Tidal Institute for British waters. It has been shown by the latter that it is possible at present to forecast about half of these non-storm effects, providing that one is supplied with a substantially accurate forecast of the distribution of atmospheric pressure.

HALF a century has been spent by the Institute of Chemistry of Great Britain and Ireland in increasingly effective service to the community as well as to the profession, and the intention of its members to continue vigorously in the same service is apparent. At the fiftieth annual general meeting, held on Mar. 1, in the unavoidable absence of the president, Prof. A. Smithells, Mr. E. R. Bolton, vice-president, read the presidential address, in which the importance of the continued loyal co-operation of all the members in this direction was emphasised. The membership has increased during the past year by 202, the roll of fellows and associates now totalling 5388. The associateship is a recognition not only of competence but also of personal acceptability; adherence to the code of professional ethics, moreover, is a sign of a definite orientation towards the highest ideals of the professional man. The determination to keep Great Britain in a leading position in chemical industry, evident in recent developments among our greatest manufacturing concerns, has created an unprecedented stir in centres of chemical education; the address referred to the desirability of convening a conference to consider generally the education of the chemist. It has been a function of the Institute to make representations to public authorities whenever it has appeared that there was inadequate understanding of the aims of, or of the responsibility involved in, the work carried out by professional chemists, and to protest when mean conditions of service have been offered. The existence of local sections of the Institute in the principal centres throughout the country has enriched the corporate life of the profession. Prof. A. Smithells was re-elected president for the new session.

Benjamin Leigh Smith, Arctic explorer, was born on Mar. 12, 1828, and the centenary of his birth deserves recognition for his disinterested and courageous efforts to add to Arctic geography. He graduated at Jesus College, Cambridge, attaining a high place in the Mathematical Tripos. Proceeding to the bar, he was 'called' at the Inner Temple in 1856. He lived a long span, dying in 1913, aged eighty-five years. Leigh Smith made in all five voyages to the Arctic regions. The first, carried through in 1871, in the *Samson*, was directed to exploration north-east of Spitsbergen. Two further voyages were similarly devoted to the Spitsbergen zone. In these he combined the attainments of a scientific observer with the skill of an experienced navigator, whilst both were coupled with that sense of enthusiasm which is indispensable to the pioneer. In the winter of 1880, Leigh Smith built a steam vessel at Peterhead—the *Eira*—of 360 tons burden, and 123 feet long by 25 feet beam. She had a complement of twenty-five, and was intended for a summer cruise in the vicinity of Franz-Josef Land. Much was accomplished before disaster overtook the expedition. The *Eira* was crushed in the ice on Aug. 31, 1881, and sank. The crew built a hut of turf and stones and wintered, along with their leader, living for the most part on walrus and bears. In June following they left in boats, reaching Novaya Zemlya, where relief was available. At the anniversary meeting of the Royal Geographical Society in 1881, the Patron's Gold Medal was awarded to Leigh Smith on the grounds (announced by Mr. C. R. Markham) that he had made important discoveries along the south coast of Franz-Josef Land, establishing new starting points for polar research; and for previous geographical work in the Arctic regions, all of which had been carried out entirely at his own expense and were personally directed. There is a portrait of Smith in the National Portrait Gallery, by Stephen Pearce.

An interesting glimpse of primitive Europe still surviving is afforded by the story of the career and death of Samuele Stocchino, quoted from the *Corriere della Sera* by the *Times* on Feb. 27. Stocchino was the terror of Nuoro, the wildest province of Sardinia, and is known to have killed eleven men in vendetta besides having committed many minor outrages. He was thirty-two years of age, and the son of a brigand who was sentenced to twenty years' penal servitude. Stocchino behaved with conspicuous bravery during the War, but at its termination took to the mountains to carry on his vendettas. He has now been shot by the carabinieri after a hunt lasting for eight years. He was finally caught in an ambush, and for some time his body lay where it fell beneath a tree. His relations, belonging to eleven families, all dressed in black, filed past it in procession, each touching the left foot of the body in passing, it being the popular belief that by so doing the doom overhanging the family was averted. Pieces of the brigand's clothes were distributed to serve as amulets. Finally, the population of Nuoro sprinkled salt and dry olives on the threshold of the 'cursed' house where the brigand was born as a propitiatory rite. The use of salt as a protection against evil influences is interesting. It will perhaps be remembered that in a matrimonial case heard a year or so ago in Devonshire, one of the grounds of complaint by the husband was that his wife, believing him to have bewitched their child, always sprinkled salt around his chair.

Mr. A. J. B. Wace communicates to the *Times* of Feb. 27 an account by Prof. Persson of the excavations of the Swedish Expedition in Greece at Dendra, at the foot of the Mycenæan citadel of Midea, in Argolis. A cemetery of important rock-cut chamber tombs has been excavated, two of them being found to contain funerary offerings such as are usual in better-class tombs of this type and dating from the latter end of the fourteenth century B.C. A third tomb was of unusual size and was immediately apparent to be out of the common. The entrance passage, hewn out of the rock, is 60 ft. long and 6 ft. wide. On its floor, which lies 17 ft. below the surface, was a mass of stones from the wall barring access to the door, and under this lay a female skeleton, accompanied by a long bronze pin, spindle whorl, and ornaments in glass paste once masked with gold leaf, which had been left by plunderers of Mycenæan times. In the chamber under two great stone slabs was found a collection of thirty-three bronzes packed one within the other, and brilliantly patinated in green, blue, and brown. These included six large jugs, seven bowls, four tripods, five lamps, a six-pronged fish-spear, a sword, two knives, and two razors. Several are decorated with delicately engraved flowers or shell-fish, others with geometrical patterns. Many of the objects retain their wooden handles.

This find is one of the richest of early bronzes yet made in Greece. It has been possible to fit together some of the many fragments of limestone on the floor. They have proved to be a sacrificial stone, and further apparatus of sacrifice, of which other evidence appears in traces of smoke on the walls and a quantity of charcoal. On the floor was a bronze sword with a hilt ornamented with glass beads in hundreds, boars' tusks cut and pierced to sew on a leather helmet, an iron stud from a sword hilt, and hundreds of small

Science and History.

Classics of Modern Science (*Copernicus to Pasteur*). Edited by Prof. William S. Knickerbocker. Pp. xiv + 384. (New York and London: Alfred A. Knopf, 1927.) 18*s*. net.

THERE is a great problem facing the study and the teaching of history throughout the civilised world. On one hand, it is more and more of a commonplace that we must study history, and that the historical way of looking at things is essential to right action. On the other, there remains the greatest divergence as to what sort of history should be studied. Nay, more; on the subject suggested by this book there is not so much divergence as an almost complete severance and ignoring of one side by the other in the discussion. The editor begins by quoting Du Bois Reymond to the effect that "the history of science is the real history of mankind." He cordially accepts that statement, and adds that the sooner we realise it on a grand scale, the more we shall hasten the happiness of mankind. Now, what Du Bois Reymond held was that the real history of mankind is simply ignored by all those who are generally recognised as 'historians.' It is not that they criticise or oppose it 'in its place,' but they say that it is not their business; it is not what they mean by history.

This is the extraordinary position, and as it is impossible to believe that such a misunderstanding or divorce between two connected aspects of human thought can be permanent, one welcomes any modest and practicable attempt to make a bridge. This book is distinctly of the bridge-building kind. It is compiled by a professor of English in the University of the South, U.S.A. It consists of typical extracts chosen from the writings of thirty-six men of science from Copernicus onwards, and the preface ends by commending science as one of other efforts towards "bettering man's estate." The author holds that for English courses, where emphasis is laid on ideas as inspiration in writing, men of science, being necessarily clear thinkers, have provided excellent illustrations of straightforward and coherent writing.

From this point of view, the book, so far as we know, is unique in English, and deserves special attention as a fresh approach to the problem from which we started. There are two other methods now in progress for bridging the gulf, and it may be interesting to put them side by side with this. One is that going on within the ranks of men of science themselves, which found expression a few years back in a resolution, and a committee appointed by the British Association, aiming at including some teaching of the history of science in the last two years of the science course at school. The book, compiled by Mr. Whetham and his daughter, called "Cambridge Readings in the Literature of Science," and published by the Cambridge University Press, would be useful material for students of that kind rather than for the English courses which Prof. Knickerbocker has in mind. The Cambridge book traces the development of definite subjects; the structure of the universe, the nature of matter, and the development of life are the topics chosen as being of transcending importance. This plan involves much more detailed and technical matter than would be suitable for general reading, and the book thus becomes clearly one for those pupils who make natural science their principal study. It does not help us directly to solve the problem of the bifurcation in history.

A third method remains, which is happily gaining ground among the writers of history textbooks. This is to introduce, at the most telling points in the ordinary political narrative, some account of the contemporary development of thought, especially in the sphere of scientific discovery. It was, in fact, an anomaly too flagrant to be defended, to teach Greek history without Pythagoras or Archimedes, the Renaissance without Leonardo or Galileo, the modern world without Newton or Darwin. If once a few such *points de repère* can be secured, the battle is more than half won. Interest once aroused, and the right of place granted, it is inevitable that inquiry spreads and teachers and taught alike begin to ask what led up to th achievements of these great men, and how has the work affected later thought, and, more especially, the evolution of society.

The last point is capital, and the orthodox historians are perfectly right in asserting that social structure is the proper subject of history. They are wrong in ignoring the part which science has played in forming it. We, on the side of science, shall fail if we do not make clear the growingly preponderant rôle which science has played in that direction. Specialism on both sides has proved the most serious obstacle to a better mutual understanding. The political historian is more and more absorbed in the overwhelming mass of his documents, and is apt to think that the attempt to set up such connexions as we have here in mind is illegitimate or at the best premature. . . . It is all so complicated and obscure; we do not know enough to 'generalise.'

What, however, we do know unquestionably, is the steady and triumphant progress of science, or organised thought, and it is a very proper subject of inquiry to consider the effects of this on the life we live as political and social beings. On the other hand, the scientist has his own special line of research, increasingly narrow as a rule, and is content to leave social reactions to 'historians' proper.

Hence the fatal gap which must be bridged, if science as a social and intellectual force, and history as a synthetic record of man's evolution, is ever to be realised. It will be clear from the examples given that the goal must be slowly and variously approached. But in the pioneer stage of any undertaking a special welcome is due to those who have the same vision of the goal, who wish to follow the same path as ourselves and actually begin to blaze a track through the jungle. For that we thank Prof. Knickerbocker, and wish his book success.

Watt: the Man and his Engine.

James Watt and the Steam Engine: the Memorial Volume prepared for the Committee of the Watt Centenary Commemoration at Birmingham, 1919. By H. W. Dickinson and Rhys Jenkins. Pp. xvi + 415 + 105 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1927.) 63*s*. net.

JAMES WATT died on Aug. 19, 1819, and to commemorate the centenary of his death energetic steps were taken in Birmingham. It was hoped that sufficient funds might be collected to erect a Watt Memorial Hall in Birmingham, to found a 'Watt Chair' in engineering at the University of Birmingham, and to publish a memorial volume. Commemoration proceedings lasting for several days were successfully held in Birmingham in September, but the sum collected fell far short of the amount aimed at. Finally, it was decided to found a 'James Watt Fellowship' in engineering, and for this purpose a sum of £5000 was handed over to the University of Birmingham. A portion of the remainder was used for this memorial volume, and the balance is in trust until such time that it may be used towards the objects for which it was originally subscribed. Urgent as is the need for a hall and buildings devoted to engineering and kindred sciences in Birmingham, it may be said that the volume under review is probably the fittest memorial to the great engineer.

A life of Watt was, apart from the centenary, long overdue. It is more than sixty years since Dr. Smiles wrote "The Lives of Boulton and Watt" in a popular style, and it was in 1854 that Muirhead published his work on "The Origin and Progress of the Mechanical Inventions of James Watt," dealing largely with letters and patent specifications. These are the only previous comprehensive works on the subject, although there have been numerous smaller popular books and papers dealing with some particular phase or side of the engineer's life.

The Committee was fortunate in obtaining for the memorial volume Mr. H. W. Dickinson and Mr. Rhys Jenkins. It had at hand a very great number of records, letters, and drawings, and the examination and selection of these in itself has been a great task. The three chief sources of information on the subject have been the Boulton papers, now in the Assay Office at Birmingham, the papers relating to Watt belonging to Major J. M. Gibson Watt—the present representative of the family, and kept at his seat at Doldowlod, Radnorshire—and the Boulton and Watt collection in the hands of the City of Birmingham. The numerous footnotes in the volume, and the many reproductions of original drawings, make one realise what a mass of information has fortunately been preserved having a direct bearing on the steady growth of the greatest implement which has helped forward the civilisation of the world. We share with the authors their regret that the volume finishes with the retirement of Watt from active business in 1800, but it is a matter of congratulation that one is now able to follow even so far the progress of the man and of his work.

The book is divided into these two sections, the first and much smaller one dealing with "Watt the Man," while the much larger portion is devoted to "Watt and the Steam Engine."

The first portion is a very human document, and places before one a vivid picture of Watt in his younger days; and although, as stated, he was shy, modest, and unassuming, yet he was capable of attracting the friendship of men of position in the scientific world much higher than he then occupied. This trait in his character, in spite of the fact that later in life he became apparently less amiable, seems to have remained with him to his great advantage throughout his life. What must be fully appreciated is the fact that Watt was never apparently strong in health, and the arduous work he did in London in 1755–56 probably further weakened him. On his return to Glasgow he was fortunate in the circle to which he was admitted, including as it did so many eminent scientific men, several of whom were to remain his friends for many years. Perhaps it is due to the story of his watching the kettle, but many will be surprised when it is shown that he was twenty-nine years of age before the idea of a separate condenser, rightly said to be the greatest single improvement ever made in the steam engine, came to him. Two years after this he became a land surveyor, about the same time making the acquaintance of Dr. Roebuck, of Carron Works, and the following year meeting Matthew Boulton in Birmingham. It was the help and acquaintance of these two men that supplied what Watt lacked. Perhaps it was the financial difficulties that the former found himself in that even helped matters forward, for Watt and the engine he had built at Kinneil were transferred to Birmingham in 1773–74, and progress from this time was slow, it is true, but steady and ever growing under the guiding hand, encouragement, and advice of Boulton. The progress of the world would probably have been delayed had Watt found remunerative employment as a surveyor, or had he accepted appointments offered him in Russia shortly before this time.

The partnership with Boulton and the twenty-five years' life given to his patent extended from 1775 to 1800, and this period covers the connexion Watt had with the development of his engine and its details. In spite of the strenuous and anxious time he so often had, which his letters so clearly show, he still was able to take interest in other work. It was, in fact, during this time that he brought out the copying press, was interested in bleaching by chlorine, and investigated the composition of water. On the latter the authors' researches have not thrown any additional light.

The help Watt received from Boulton is ever in evidence, and, as the authors point out, Boulton in writing in 1769 to him, said, "I do not intend turning engineer," but his sound practical advice on engineering points was often of the greatest assistance to the inventor, and one can only regret that Watt in 1788 did not give, apparently, the financial assistance Boulton then required and would have liked to have received.

The chapter on Watt's life in retirement is short, but renews the regret one has that the efforts made to purchase for the nation his house at Heathfield were unsuccessful. One cannot, however, but be grateful that the room which was his workshop has been removed in its entirety to the Science Museum, South Kensington, and that it is under the care of one of the authors of this volume.

The second section of the book is of the greatest interest to engineers. It first of all deals in chronological order with the engines built under Watt's patent. Later it is shown that very little of the actual work was done at Soho in early days; it was not until 1795, indeed, that any castings were made at the new foundry. The procedure was for drawings to be made by Watt, and the various parts to be made in different localities, and the whole erected on the final site. Watt produced these drawings during nearly the whole of the time under review at his house at Harper's Hill, less than half a mile from Birmingham Town Hall. A very large number of these plans is reproduced, and with the copies of original drawings of details will be studied with interest by all who are attracted by the history of the development of the steam engine.

The developments of the various parts of the engine are dealt with in great detail. These show that although it is said with truth that Watt, after his patent, "made no change in principle, no improvements in the direction of securing increased economy of steam," yet he was ever working on perfecting these details and supplying other improvements of working. These, which are fully dealt with, and of which the construction is shown, include the valve and its gear, parallel motion, the governor, the indicator, etc. It seems somewhat strange that more attention was not given to the efficiency of the boiler, for at first, in Cornwall, where most business was done, payment was at the rate of one-third of the saving made in coa consumption over that used by the old atmospheri engine. If more had been done in this direction

Watt might have overcome his dislike for greater pressures.

The question of the application of the crank to Watt's engine is considered at some length, and the steps he took in devising methods of producing means of avoiding it for 'rotative' engines is also dealt with comprehensively. It is interesting to note that in the four years after 'Pickard's' patent had run out, in 1792, only six engines with cranks were built by Boulton and Watt, the others being still fitted with the sun and planet motion. Watt was naturally dependent largely on his staff. Murdock, both as a craftsman and inventor, is well known, but interesting notes are included on Southern and others not so well known, and on certain engineers who were engaged in different directions. One would have thought that Rennie would have been included in the former list. The "Directions for erecting and working the newly invented steam engine," issued in 1779, are given in full.

The book is well produced, but its size, which is unavoidable, makes it one for the table rather than for the hand.

The Plague in Shakespeare's Time.

The Plague in Shakespeare's London. By F. P. Wilson. Pp. xii + 228 + 16 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1927.) 12*s.* 6*d.* net.

THIS work aims at narrating in detail the history of the plague in London in the early part of the seventeenth century. It is based on materials supplied by contemporary books and documents. The story opens with a brief account of our modern knowledge of plague, and contrasts this with the many and fantastic views held in Shakespeare's time of the cause and cure of the disease.

Plague has been a powerful stimulus in bringing about social reforms and in developing and shaping our ideas and laws on public health. The great mortality among the humbler classes during the prevalence of the Black Death in 1348–49 compelled and initiated reforms which ultimately led to the emancipation of the working classes. It was the destruction caused by plague which stirred the Government of the day to draw up and enforce orders to stay the disease. A very interesting account of the rise and development of the plague orders from their inception in 1518 is detailed in the second chapter of this book.

Among the permanent officials who were responsible for the control of plague epidemics, the brunt of the work fell upon the constables. They had to report the true number of persons who died of the disease; they had to shut up and mark infected houses and arrest "wandering beggars and idle persons." If they neglected their duties they were severely punished; at the same time they were in great danger of contracting infection. The places of casualties were quickly filled by deputies, since acceptance of the post was compulsory, recalcitrant citizens being brought before the Lord Mayor and duly punished.

When plague became epidemic certain temporary officials were appointed. For example, in 1583 each alderman was required to choose monthly two substantial and discreet citizens to be surveyors in each parish. But in May 1609 and afterwards, examiners were appointed for two months, and those who refused were imprisoned "until they shall conform themselves accordingly." The duties of the examiners were to take care that all orders were duly observed; they had to look for infected houses and to appoint and supervise the warders, searchers, and other minor plague officials.

The sanitation of London in Shakespeare's time was very primitive. It closely resembled that of an eastern city of to-day. The most potent factors in causing the plague were the great overcrowding, and the character of the houses. For example, a proclamation of Sept. 16, 1603, complained of the crowding of dissolute and idle persons in small and narrow rooms, and ordered all houses infested with multitudes of dwellers to be razed to the ground and not to be rebuilt. All attempts, however, to check the growth of London were in vain, and, far from remedying the evils, led to gross overcrowding and the erection of mean hovels in holes and corners of the city and suburbs.

Another potent cause of the trouble was the foul condition of the streets. The duty of cleansing the streets devolved mainly upon householders, but partly also upon scavengers and rakers. In Shakespeare's time two scavengers were appointed to each parish and held office for a year. Like the constables, they gave their services willingly or unwillingly for nothing. Their office was not menial; they were citizens and householders, men of some importance in the parish, civic dignitaries. They did not clean the streets themselves, but were responsible for the rakers who did. The work does not seem to have been done efficiently, for sensitive persons complained of the dunghills which pestered narrow lanes and alleys. The pudding wives and tripe wives were accustomed to throw into the channels, paunches, guts, and entrails, and also the water in which these were boiled.

Citizens were incredibly careless in disposing of carcasses. In 1578 it was found necessary to forbid them to throw out of doors any dead dogs, cats, whelps, or kitlings. In 1625 carcasses of horses, dogs, and cats lay rotting in Moorfields, Finsbury Fields, and elsewhere about the City. No wonder, then, that the streets of Elizabethan and Jacobean London were thronged with dogs. Many parishes supported a dog-killer of their own. We are quite prepared to accept, therefore, Defoe's estimate that forty thousand dogs were killed during the plague of 1665.

In such circumstances, rats, whether dead or alive, attracted minor attention, even as they do in an eastern city to-day. There were, however, we are told, many ratcatchers in Elizabethan London who, according to Richard Deering's "Madrigal of London Cries," shouted in the streets, "Rats or Mice. Ha' ye any rats, mice, pole cats, or weasles ?" Or "Ha' ye any old sows sick of the measles ? I can kill them, and I can kill moles, and I can kill vermin that creepeth up and creepeth down and peepeth into holes."

The picture of an eastern city to-day is completed when we learn that London was "a City of kites and crows." In these days in England kites and ravens were protected birds, because they were such excellent scavengers. Kites were so bold in London, it is said, that they snatched bread out of the hands of children while they were eating it on the streets.

What a reformation has been effected in our habits since these days. In this process we have expelled from our cities not only the kite, the carrion crow, and the black rat, but also with them the plague, relapsing fever, cholera, dysentery, and other diseases, now often called tropical diseases, but in truth diseases peculiar to a primitive state of social and economic development.

Much might be said about segregation as that measure is revealed in this carefully compiled work, but space forbids this. Nevertheless, a passing reference must be made to the Pest House, an illustration of which is reproduced on p. 82. A reprint of a map published in 1682 shows the situation of this building. The site, Mr. Wilson states, is a little north of the existing buildings of the French Protestant Hospital, a few hundred yards up Bath Street on the left-hand side as one walks from Old Street.

Not the least valuable parts of this book are the last chapters, which give a detailed account of the progress of the plague in London from 1603 to 1625. This account is enlivened by sundry references to contemporary history, and is illustrated by excellent reproductions of some of the original Bills of Mortality.

These chapters are followed by notes on a number of matters referred to in the text. Then follows an Appendix divided into two parts. Part I. deals with the Bills of Mortality of the sixteenth and early seventeenth centuries, the machinery which produced them, and an estimate of their trustworthiness. Part II. is concerned with an estimate of the population of London in the early seventeenth century.

Readers will find this book not only interesting but also a valuable work of reference to original documents which have a bearing on the plague in Shakespeare's time. The author and the publishers alike are to be congratulated on the excellence of their work.

Education in Hygiene.

(4) *Towards Health.* By Prof. J. Arthur Thomson. Pp. viii + 242. (London : Methuen and Co., Ltd., 1927.) 7*s.* 6*d.* net.

THE replacement of instinct by reason in the ordering of human affairs has not proved an unmixed blessing where the health of the individual is concerned. Instinct unerringly acts not only for the benefit of the individual but also of the race ; too often reason is short-sighted, and what recommends itself to reason as convenient and pleasant for the moment proves in the long run to contain seeds of disaster. For example, the discovery by primitive man of the art of cooking was undoubtedly an immediate benefit. Many new substances were rendered available as foods, and the nutritive qualities of others multiplied. But the result has been that the mammalian organs evolved to deal exclusively with raw fibrous material have become to a large degree superfluous. Our complicated and elongated alimentary canal remains a cumbrous and inconvenient heritage. Our teeth, no longer required for the purpose for which they were evolved, have lost their survival value. They have consequently lost their resistance to decay, and are the most vulnerable of our organs.

The returns of industrial sickness and the results of school medical inspection both reveal an appalling amount of preventable illness in the population. It is largely the result of ignorance. For example, a school dental service has been introduced, not alone as a means to cope with the ravages of dental disease in children, but also as a preventive measure. But less than half of the parents take advantage of it at all, and of the small proportion who do, the majority take advantage of it too late to save teeth which are already decayed. So to the provision must be added a propaganda organisation.

The problem of the hygienist is now to spread amongst the population the necessary knowledge which all must have to enable them to avoid the insidious menaces which are the accompaniments of modern social life " The people perish for want of knowledge." Therefore the ministries and the municipalities are concentrating upon health propaganda and health organisation. To aid the good work there is a brave outpouring of books, amongst which the four we have before us stand out as typical examples, each approaching the subject at a distinct and widely differing angle.

(1) Dr. Mumford sets out in " Healthy Growth " the untiring and conscientious work which he has carried out for many years in observing the growth and controlling the health of the boys at the Manchester Grammar School. He reviews the attempts made to use the mass of statistics which he has collected One by one, accepted formulæ were tried and finally discarded in favour of the criterion of *time increment*. Some consideration of the results has already appeared in our columns (NATURE, May 8, 1926, p. 656). Though convinced that there is a definite relation between physical and mental growth. Dr. Mumford has experienced great difficulty in demonstrating it satisfactorily. He now thinks that he is able to do so by the use of an expression for physique consisting of the weight divided by the height multiplied by the square of the chest circumference. This he terms the 'buoyancy index,' $W/(H \times C^2)$. Groups of advanced scholars compared with groups of retarded scholars show positively that better buoyancy is associated with high mental performance. But when the advanced scholars are compared amongst themselves, it is found that those who obtain the highest marks have the least buoyancy. This somewhat anomalous result can be interpreted only by the assumption that the possession of a certain degree of physique is necessary for superior mental development, but competition at our secondary schools is so severe that those who excel in examination do so only at the expense of their physical development. Should this prove on further investigation to be well founded, the system of competitive examinations must receive a mortal blow.

" Healthy Growth " is by no means an easy book to read, but it is necessary for all those who have to deal with the problems of the adolescent youth. In view of what comes later, it is a remarkable achievement to have written a treatise on the growth of adolescents without one reference to diet

(2) " Personal Health " is a popular text-book written by the professor of hygiene in the Ohio State University. It is beautifully produced and profusely illustrated. The method followed is to take the bodily systems in order and to discuss influences which promote and hinder their efficiency. It is well done, and the final result is summed up in fifteen rules for personal health, which are well balanced, sane, and will be supported by all hygienists.

It is sad to reflect upon the numbers

> " Who have died because they never knew
> These simple little rules and few."

Those connected with diet are excellent, and keep this much-debated subject in its proper focus. They are: Rule 7. Avoid overeating and overweight Rule 8. Get back to Nature in the matter of foods you eat. Remember that Nature's food products are grains, vegetables, fruits, nuts, meat, milk, eggs, and water. Rule 9. Select your food widely from the above; get a certain part fresh every day, *i.e.* not canned or bottled. Drop fads and chew well. Do not diet except on medical advice.

Prof. Hayhurst's first rule is ' Ventilate every room you occupy," and his fifteenth is " Keep serene no matter what happens."

Unfortunately, all such rules are counsels of perfection and cannot always be followed even when known. We were travelling to Cambridge lately by rail, and were careful to open the window by which we were sitting. Presently a fiery-faced don came across from the opposite end of the compartment and with some emphasis pulled up our window. After the air had become sufficiently close we ventured, when his attention was distracted, to drop the window ever so little. So soon, however, as our friend perceived the freshening atmosphere, he made an infuriated rush for the window and banged it up again. The net result of this deplorable journey was that we had obeyed the first rule of health very imperfectly, and the last not at all.

(3) "At the age of forty every man is either a fool or a physician." Therefore the presentation of the point of view of the intelligent layman is very welcome Mr. Barker, however, proves disappointing. His thoughts run chiefly on food. He makes great play with the comparative mortality tables furnished by the Registrar-General. He points out that doctors as a class suffer much more from digestive and renal diseases than do agricultural labourers From this he makes the deduction that doctors do not understand the principles of health, particularly in relation to diet. It has not occurred to him that the corollary to this deduction is that the agricultural labourer understands more about health than does the doctor.

The truth is that the labourer's vocation forces him to adopt more or less a healthy mode of life while the doctor's condemns him, *malgré lui*, to an unhealthy one. The general practitioner lives a life unapproached for stress and hardship. During periods of epidemic prevalence he is constantly in contact with disease He rarely has time for meals and must bolt his food. His day's work extends to twelve or fourteen hours without intermission. He cannot afford to take the rest he enjoins upon his patients. When he feels his temperature rising, he alone must not succumb, and therefore doses himself with antipyretics and stimulants and sets out in all weathers to visit the sick. When, dead beat, he retires to bed after an exhausting day, it is ten to one that he will be called out again into the bitter night. Living at this pressure, it is inevitable that digestion and arteries suffer. If Mr. Barker took the relative mortality statistics of soldiers and civilians, he would very probably find that the former die more frequently from bullet wounds; his deduction would be that the soldiers die because they do not understand fire-arms

If Mr. Barker were right, what would be the answer to the question asked by Sir George Newman in his latest report: "Why is infantile mortality lowest in doctors' families?"

Mr. Barker gives the ideal regime he himself follows, which has restored his own personal health. Here is an extract: "My breakfast consists of a portion of bran porridge, made of equal weights of coarse oatmeal and ordinary bran cooked two minutes."

By all means the book should be read; more than half of it consists in interesting quotations from authorities ancient and modern, which make it a veritable medical anthology of the *vis medicatrix Naturæ* But it is not wise to attempt to follow the advice it contains without first consulting the family doctor

(4) Finally, we have a book from the fluent pen of a distinguished biologist. Naturally, it introduces a most valuable element into our discussions on health. Like all Prof. Arthur Thomson's books, it is written in that flowing, easy, informative style which makes them such a pleasure to read. He does not think it necessary to devote much space to food—only 2½ pages out of 232. He focuses attention bravely upon the problems of heredity, of birth-control, of sex education, and other highly controversial questions. But his urbanity and fairness are such that he can step even on our favourite corns without greatly annoying us. The biologist sees the species rather than the individual. and reveals the important truth that much which is done socially for the weakly individual is not in the interest of the race as a whole. On birth-control, Prof. Thomson conducts a gentleman's controversy with Prof. Pembrey, but so just is he to his opponent, and so fairly does he state the latter's case, that we leave with the impression that upon this topic at least the physiologist is the better biologist.

The Lady Hygeia must often be at bitter feud with her sister the Lady Eugenia. It is useful to be reminded that the hygienist does not necessarily have the last word.

Animal Biology.

Animal Biology. By J. B S. Haldane and Julian Huxley. (Clarendon Science Series.) Pp. xvi + 344. (Oxford: Clarendon Press. London: Oxford University Press, 1927) 10s. net. Cheap edition, 6s. 6d. net.

DURING the last ten years there have been important changes in the biological sciences. The classical divisions into which animal biology falls are physiology and zoology. In both these subjects it is increasingly felt that a wider scope is necessary. In physiology this widening process is already advanced, as the flourishing condition of its daughter subjects, such as biochemistry, testifies. The position of zoology, on the other hand, is at present difficult. Modern zoology is founded upon the work of Darwin; yet although his work primarily depended upon observation of the living animal, its consequence was to make zoology drift more and more towards pure morphology. Detailed and comprehensive knowledge of animal types and their anatomy has of course been vital to zoology, but at the present time the sterility of the old methods, which restricted investigation to the comparison of the anatomies of dead organisms, is clear. It is not that morphological methods are unsound, but that the real problem of the living animal is how it lives and how it has been evolved, and to study this one must understand not only its morphology but also its function. It is not perhaps too much to say that such understanding demands a greater knowledge of physiology and the principles of physics and chemistry than the average zoologist has until recently possessed.

It is essential, then, that the zoologist should study function as well as form in the animals he observes. How necessary this is can be seen when one considers that a Lamellibranch mollusc feeds with 'gills,' so called, which have no respiratory function, and that its 'liver' has yet to be shown to possess *any* function in common with the typical organ of the vertebrate. The lamellibranch liver forms no secretion; it is an organ of phagocytic ingestion and of absorption. A digestive organ on a plan more different from a vertebrate liver is hard to conceive.

As for physiology, its intimate relation to medicine has resulted in its restriction almost entirely to the study of one single group—the vertebrates. Its great recent advances have now brought it to the stage when many fundamental generalisations are being made; but the process of generalisation is seriously handicapped by lack of knowledge of other types. There has been a tendency to consider animals other than vertebrates merely as 'lower animals' of simpler organisation, and with this has come the implication that the physiology of these simpler organisms would not differ fundamentally from that of the vertebrates. The fact that the animal kingdom consists of many separate phyla which have evolved along different lines for untold ages has not been fully appreciated

The arthropod has evolved independently of the vertebrate and is in its own field just as highly developed. We have no reason to suppose that this tremendous morphological divergence has not been accompanied by as vast a physiological divergence. Yet it is common to find in textbooks a photomicrograph of an insect's muscle illustrating an account of the physiology of striped muscle, although almost all such work has been done on vertebrates Now vertebrates and arthropods having been separate for so long, and having in all probability evolved striations in their muscle quite independently, there is no reason to assume *a priori* that we have similar contractile mechanisms in both cases. If we find that the processes actually are similar in such cases, it indicates a remarkable restriction in the types of physiological mechanism which can be arrived at by protoplasm. The recent work of A. V. Hill and others has shown that certain fundamental processes in contraction do, in fact, appear to be identical in the muscles of many different phyla.

A mechanism of this kind, which appears to depend upon a fundamental property of protoplasm, is obviously of far greater importance than one which is merely peculiar to a single group, the vertebrates, and the fact that several mechanisms common to the whole animal kingdom have recently been discovered is one of the most important steps made in physiology. Such discoveries simplify the whole problem, and the physiology of man himself can be elucidated by the study of other organisms of widely different origin.

It seems necessary, then, that the zoologist in his training should learn something of the physiology of the types he studies, and the physiologist should be familiar with the variety of animal forms and able to relate their physiological processes to those of the vertebrate. The question is, How is this to be done? The ideal condition is plainly to awaken a broad interest in the relations between the various sections of biology while the student is still young. It is at this point that such a book as "Animal Biology," by J. B. S. Haldane and J. S. Huxley, will prove extremely valuable, for the authors have succeeded admirably in co-ordinating the several branches of zoology and physiology.

The book opens with an introductory chapter based on the physiology of the frog What knowledge of function the student has is connected with his own body, and from man to frog is an easy step in the development of ideas regarding function in different organisms. It is much better to begin in this way than to enter into a preliminary discussion of Amœba, protoplasm and its properties, a matter unfamiliar and of extreme complexity.

The next chapter gives a general account of development based on that of the frog, gametogenesis, Mendelian heredity, evolution, and natural selection. The inter-relations of these subjects are well expressed, and the explanation, which is much helped by the many illustrations, should counteract the tendency to treat each subject as separate.

There follows a chapter on metabolism and the building up of protoplasm. It is a pity this is so short, and a brief outline of the chemical nature of the proteins, carbohydrates, and fats would easily be grasped by the student and would help to give him an idea of the molecular basis of protoplasm.

The next few chapters deal in detail with elementary physiology—respirations, functions of blood, digestion, excretion, and the nervous system. The whole book, especially in its early chapters, contains an amazing amount of information in a small space and repays attentive reading

An interesting chapter on internal environment considers the composition of the plasma and the function of dissolved substances, endocrine secretion, and immunity. A clear and interesting account is given of the relationship of development and regeneration, and the effect on these of environmental factors. Chapters x. to xii are very good reading in an easy style. The proofs of evolution are given, the possible modes of evolution criticised, particularly from the point of Mendelian heredity and the influence of natural selection, and finally the results of evolution discussed and compared. One of the most interesting features in the book is the table of comparative sizes of organisms (pp. 276-280). It comes as a shock to realise the immense variations in size met with in Nature. To choose a few ·

$10^{57} \times 1 \cdot 8$ = minimum weight of universe.
$10^{27} \times 6$ = weight of earth
10^{10} = big trees of California
10^{-14} = smallest filter-passing organism.
10^{-18} = hæmoglobin molecule
10^{-27} = an electron

The book is well got up ; there is an index and glossary of technical terms, and the illustrations are numerous and well reproduced The price (6s. 6d) seems very reasonable. It is hard to find anything to criticise even in details : the plasma of land animals is more near to sea-water diluted to 4 to 5 times its volume than to 3 times (p. 159) , and it is scarcely true to imply (p. 172) that any severed piece of a Protozoon can regenerate the whole organism, since regeneration in Protozoa depends absolutely on the presence of nuclear material in the segment.

To sum up, the book is an excellent one, and could be advantageously read by the advanced worker as well as the student. One feels, however, that at the present time it will be of more value to the university student than to schoolboys under 16½, for whom it is apparently intended. The book is certainly not beyond the grasp of an intelligent boy, but there are so far few schools where the general scientific education would be sufficiently advanced at that age for such a book to be fully appreciated. One hopes that soon it will be otherwise. C. F. A. P.

Science and Psycho-Pathology.

Psychopathology : its Development and its Place in Medicine. By Dr Bernard Hart. Pp vi + 156. (Cambridge · At the University Press, 1927) 7s. 6d. net.

IT is a fortunate circumstance that works of a strictly technical character in which no concession is made to easy understanding prove sometimes to have interest and value for a circle far wider than that to which they are primarily directed This book is addressed to a medical audience, its point of view is that of an adept in a special branch of medicine, and it keeps to its theme with uncompromising closeness Nevertheless, through a happy combination of its subject with its author's philosophic temper and expository skill, it is a work that anyone interested in the general field of science may be advised with confidence to read.

The book is made up of three parts. The second and third parts are entitled respectively "The Psychology of Rumour" and "The Methods of Psycho-therapy," and are comparatively short essays. The latter is of chiefly technical interest ; the former is an examination of the psychological nature of testimony, a theme admirably suited to the easy lucidity and firmness of touch that are characteristic of Dr. Hart's writing

The greater part of the book is occupied by three lectures on the development of psycho-pathology and its place in medicine. These were the Goulstonian lectures delivered before the Royal College of Physicians of London, and are thoroughly worthy of their author and of the occasion of their delivery In these lectures there is given a comprehensive and judiciously compressed review of the efforts of medicine to explain and to treat the common class of disorders now universally regarded as of mental origin and known as the psychoneuroses. From this review there emerges the fact that the only system of doctrine which even affects to deal with the whole field in a radical and comprehensive way is that which has the rather awkward name of psycho-analysis and is the work of Sigmund Freud. It is naturally, therefore, to a critical examination of this system that Dr. Hart chiefly directs himself.

It may be said at once that the discussion is the best that has been published on a very thorny topic. Dr. Hart is well equipped for his difficult task, he has knowledge and independence of mind, and is quite free from those defects of advocacy or detraction that have spoilt so much writing on this matter. He gives a summary but adequate general account of the Freudian system, and examines with especial care the claim that is made for it of being in strict accord with the methods of science. It may perhaps be well here very briefly to remind the reader that the work of Freud in psychology falls naturally into three broadly distinct divisions—a somewhat arbitrary separation that makes consideration of the great bulk of the material rather less difficult In the first place comes the work on the elementary mechanisms of the mind by which were elucidated such processes as conflict, repression, and the effects a repressed system is capable of producing This work is uniformly guided by the principle that mental events are determined by the relation of cause and effect as rigidly as are physical It is already very widely accepted and has had a great influence on psychology in general Secondly, there is the evolution of a comprehensive theory of the mind which assigns a practically complete primacy in power and significance to the impulse of sex. Thirdly, there is the elaboration of a method of examining the contents and working of the mind which is at once an implement of psychological research and a method of treatment for the psychoneuroses.

This is, of course, the famous method of psychoanalysis which has come to give its name also to the whole doctrine of Freud. The claim is made for this method that it is unique in the access it affords to the mind and that it is capable of exact scientific use. Upon the justice of this claim the whole Freudian system depends. The process of psychoanalysis—to describe it very crudely—consists in the patient talking about himself and his experiences under the direction and influence of the physician. In this relation the influence of the physician must and is admitted to become very great. In view of this fact, Dr Hart points out that the psychological facts elicited by the physician can perhaps no longer be regarded as, so to say, the pure facts of observation, but should be looked upon as tainted by the physician's direction and so no longer fit material for the foundation of scientific theory. This is his principal criticism of the Freudian system, and as it is directed to the validity of the method on which the whole is founded, it is plainly fundamental. This objection is met from the psycho-analytic side by the view that the unconscious processes of the mind of which the physician is in search are characteristically refractory, and only to be influenced with the greatest difficulty. As, however, this feature of the unconscious is only to be ascertained by the process of psycho-analysis which is itself in question, the argument seems only to bring us back to our starting-point.

Of the element in the Freudian system which has aroused the sharpest dissent—the sex theory itself —Dr. Hart's discussion is a model of rational and open-minded inquiry. He finds no inherent irrationality in the theory, but although he is very sparing of *a priori* considerations in general, he seems to feel the difficulty, which perhaps comes most naturally to the biologist, of ascribing an exclusive influence in forming the mind to one impulse, and denying any influence to all the other impulses of the flesh.

The author discusses shortly the independent confirmation of the psycho-analytic doctrine that has been sought in therapeutic results, in the study of myth, and in that of insanity. In regard to the last-named subject, where of course his opinion is an authoritative one, he says that the evidence is "perhaps more convincing than in any other field, because phenomena can be observed in the speech and actions of the insane which are entirely conformable to the principles deduced from the psychoanalytic method, and in which any influencing of the patient by the physician is excluded by the nature of the case."

It has been possible to touch only on some of the topics of this invaluable review of the Freudian case. Enough has perhaps been said to show the exemplary tone in which it is written and the gratitude Dr Hart has deserved both from the critics of Freud and from the disciples of this revolutionary genius. Dr. Hart describes his ultimate attitude as one of benevolent scepticism. The cause of psycho-analysis is especially likely to benefit by such criticism as his, for it has had to contend with a curious and perhaps unique disadvantage. It has given to its advocates a new insight into motives and has enabled them to explain and to discount hostile criticism, often quite correctly, as essentially conditioned by non-rational processes in the critic's mind of which he has been quite unaware. To possess an infallible answer to opponents is not wholly to the advantage of a developing body of doctrine. It may be inspiriting to the believer, but it tends to weaken that anxious search for truth in hostile opinion which is the last gift of the scientific spirit.

Man's Early Settlements.

Peasants and Potters. By Harold Peake and Herbert John Fleure. (The Corridors of Time, 3.) Pp. 152. (Oxford: Clarendon Press; London: Oxford University Press, 1927.) 5*s.* net.

Priests and Kings. By Harold Peake and Herbert John Fleure. (The Corridors of Time, 4.) Pp. 208. (Oxford: Clarendon Press; London: Oxford University Press, 1927.) 5*s.* net.

THE results of anthropological and archæological studies constantly need readjustment and comparison, and both must occasionally be controlled by the statements of antiquity. The period under review in the present studies presents very special difficulties, for on nearly every vital point there are almost as many opinions as doctors. The subject of the third part of "The Corridors of Time" is the development of the pastoral and the agricultural peoples between about 5000 and 3500 B.C., and involves a consideration of the domestication of animals, a study of the prehistoric period in Babylonia and Elam, of the early pre-dynastic age in Egypt, and of the earliest remains at Anau in Turkestan and in Crete, with a sketch of the anthropologists' views of the races of men involved. The fourth part is devoted to an account of the early history of Sumer and Akkad and of Egypt, and a description of all those settlements which in the authors' opinion may belong to the period 3500–2500 B.C., again with a synopsis of the probable migrations of races which may conceivably be connected with the period discussed. From the Nearer East the reader passes to the Mediterranean islands and Thessaly, back to Turkestan, thence to the Danube, finally to end by the Black Sea. The handy volumes form an interesting *aperçu* of an immense period of time over a very large area, involving many different studies.

The authors are so well aware of the diversity of opinions on wide questions that it is unnecessary to discuss the many debatable questions. The pertinent criticism is rather that some questions are represented as disputed on which competent opinion is agreed, while isolated opinions are accepted as certain which should rather be presented as very questionable. The First Dynasty of Ur is placed so early as 3752 B.C., while Ur-Nina of Lagash is dated shortly before 3000 B.C., a matter of great importance for Sumerian chronology; on epigraphical and archæological grounds it is impossible, on grounds stated by specialists, to assume a gap of 700 years. Doubt is expressed as to whether the principal object of the Egyptian mines in Sinai was turquoise or copper; but mining engineers have reported with no uncertain voice on the matter, and most Egyptologists believe that *mafkat* should be translated 'turquoise.' On the other hand, Dr. Frankfort's theory of the painted pottery of Susa is relied upon as certain, perhaps on the principle *qui tacet consentit*; but M. Pottier's careful study, together with the excavators' notes, presents another, equally possible, view, and no excavator of a Mesopotamian site could argue that the layer of earth between the graves called 'Susa I.' and the 'Susa II.' level is necessarily due to an abandonment of the site.

The question of origins, with which the authors are primarily concerned, must always be fascinating, and the two schools which profess the dogmas of the single or the multiple origin are likely to subsist for some time yet. But advances are slowly made. It is now generally accepted that we have no evidence of a true 'neolithic' age in Asia, as the writers correctly remark, though they fall into the error of referring to "stone age graves at Tell el Obeid." Yet another step remains to be taken. Apart from the pastoral and agricultural communities, cities existed for trade, which was as important in pre-dynastic Egypt and in early Sumer as it ever became in later times, for only so can the astonishing wealth of both civilisations be explained. Cities like Ur contained a considerable class engaged in industry, and the population did not consist solely of "Peasants and Potters." Trade is indeed frequently alluded to in these volumes, but the hasty and partly incorrect statement about the new Indian evidence has not allowed of a just consideration being given to two vital points: (1) the extent of trade connexions and their character; (2) the kind of cultural influence exerted in cases such as this, proved beyond a doubt. The vagaries of trade, also, deserve a closer consideration, and we could wish that the doubtful theories about racial connexions of dynastic Egyptians and Arabians and Sumerians had been omitted in favour of an explanation of the manner in which evidence of a trade connexion between Sumer and Egypt first appears late in the pre-dynastic period and seems to disappear after the Third Dynasty.

The absorbing interest of this problem leads too often to that speculation about the unknown which is the bane of archæology. As Egypt and Mesopotamia gradually become defined and limited in their possibilities, North Syria, Asia Minor, Arabia become the dumping-grounds for theories. Yet what little we do know rarely favours the hypotheses. Is it really conceivable that the Egyptians were taught the art of making their stone vases by men from Arabia? Does a single stone vase in the form of a camel prove such a theory? What are the latest statements about that vase? Or again, did bedouin from the Arabian desert invade the plains of Babylonia? Every known invasion by Semitic-speaking peoples into Akkad followed the Euphrates valley from at least so far north as the Khabur, and none of these peoples were nomads straight from the desert.

The learned authors have undertaken a difficult task, and on the whole succeeded in the attempt to correlate various subjects. That their views evoke criticism is no more than they expect. The reader will not fail to appreciate the ability with which scattered matter has been collected and compressed into a form well calculated to instruct in strange lore. A second edition will probably be required; in that case some of the bad minor errors, such as Sharain for Shahrain, and Azag-Bau (an old, erroneous reading of the signs Ku[g]-Bau), some mis-statements about excavations, and some wrong citations of authorities, might be corrected.

Technology of Paints and Varnishes.

The Industrial and Artistic Technology of Paint and Varnish. By Alvah Horton Sabin. Third edition, revised. Pp. xi + 459 + 9 plates. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1927.) 25*s*. net.

THE name of Sabin is so closely identified with the technology of paint that the reappearance of this book as a new edition will give a thrill of pleasure to most readers. The book is very like the earlier edition, preserves the same general form, and aims at giving an account of the principles involved in the manufacture, application, and use of paints and varnishes. It is obvious throughout that the book bears the impress of the author's own personal experiences, and consequently some may think that undue importance is laid upon certain aspects of the work whilst other sections receive inadequate treatment. The author has very wisely forestalled criticism in that regard by quoting in his preface the amiable maxim of Erasmus, that "a reader should sit down to a book as a polite diner does to a meal. The entertainer tries to satisfy all his guests; but if it should happen that something does not suit this or that person's taste, they politely conceal their feelings and commend other dishes, that they may not distress their host." The present reviewer entirely subscribes to this view of the matter, and in doing so finds a perusal of this book not only very pleasant but also stimulating to a high degree.

The first edition, published in 1904, was chiefly concerned with the subject of oleo-resinous varnishes; since then, important developments have taken place in varnish-making, particularly through the advent of Chinese tung oil, which has entirely changed, and in Sabin's opinion not always for the better, especially in the matter of durability, the character of many of the products of the varnish maker's art.

In America, where now tung oil trees are being grown extensively, the use of this oil has long been established as an essential raw material of the industry, for it possesses properties which are unique among the drying oils. In England, tung oil has also found its place in varnish-making practice, but the extent of its use here is nothing like what it is in America.

This condition is probably due to several causes apart from the innate conservatism of the Englishman. In the early days, it was generally regarded in England as a kind of substitute for linseed oil, a view which working experience should soon show to be incomplete. It took much time, however, for people to realise that the peculiar properties of tung oil, namely, its extraordinary capacity for rapid gelation under heat, the water-resisting quality of its films, and the power it has of carrying rosin varnishes into a high quality class of product, made the oil worthy of study on its own account.

Another important point which has a bearing upon the subject is the fact that American practice is far behind European in the use of heat-treated oils. This deficiency has been responsible for a readier application in America of special oils like tung and perilla. These essentially Eastern products have long been used in the regions of their origin and have formed the basis of the remarkable Chinese and Japanese and similar lacquers. The chapter devoted to this subject is most interesting and instructive.

Naturally, one would expect reference to be made to nitro-cellulose lacquers, but the treatment given is very general and rather short, although the author subscribes to the view that the extraordinary development in these lacquers during the last few years has had an influence upon the paint and varnish industry, the full effect of which cannot yet be judged. The first use of a pyroxylin lacquer was recorded many years ago. The War brought an extraordinary demand for aeroplane dope and left a legacy in the shape of enormous plants for the manufacture of nitro-cellulose for which there was no immediate demand.

One thing has been achieved by the advent of cellulose lacquers, particularly through the agency of the enormous solvent industry which has grown up alongside: the paint and varnish industry now realises that it is a chemical industry. Proper application of this fact, with all that it implies, will do much to stimulate scientific development work all round, and to clear away the misunderstandings and uncertainties attending the 'secret' processes of the 'art,' which are a drag on real progress. As Mr. Sabin says, "the only trade secrets lie in the incommunicable intimate knowledge of the expert, and are made valuable only by his unceasing care, vigilance, and conscientiousness."

Mr. Sabin has throughout followed the historical method, and the text is freely embellished with historical comparisons. It is indeed most astonishing to realise the extent of the knowledge of centuries ago. The insight displayed by the ancients into the working of the processes they described is remarkable. The explanation of the wrinkling of paint as given by Eraclius more than a thousand years ago is almost uncanny, having regard to the present state of knowledge on that vexed question.

One closes the book with the feeling that it is unfair to dwell upon the glories of the immediate past. True it is that history is but the record of past events, which we should take, if we are wise, to mould our course in the future, but one feels rather uncomfortable in realising the extent of the knowledge of those early practitioners in this ancient art.

L. A. Jordan.

Principles and Practice of Electrical Illumination.

Modern Electrical Illumination. By Cyril Sylvester and Thomas E. Ritchie. Pp. xi + 416. (London: Longmans, Green and Co., Ltd., 1927.) 42*s*. net.

ONE of the most noticeable features of the post-War period has been the increasing recognition of the importance of illumination in modern life, socially, commercially, and industrially. Illumination for social purposes has always been appreciated for its own sake, as witness the magnificent salons of the eighteenth century with their myriads of candelabra, representing the acme of their day. The commercial value of the attractive lighting of shop windows and showrooms is of course obvious, while many of our stores could prove that it is easily the cheapest form of publicity. These reasons will not, however, explain the great developments which have taken place in industrial establishments.

In the old carbon lamp days, illuminations of one foot-candle were regarded as adequate for most purposes, while before the invention of the Welsbach mantle, illumination intensities even lower must have been normal. The change in our standards is probably due in part to the increasing demands made on visual processes in almost all occupations as a result of the ever-growing complexity of modern civilisation, together with the somewhat belated realisation of the importance of good lighting for the most efficient functioning of the eye. It is only very lately, and largely as a result of war conditions and problems, that public attention has been focused on such matters as industrial fatigue, visual acuity, and the comfort of the worker in relation to output, spoilage, and accident. In Great Britain we have the evidence which is being provided by such impartial organisations as the Industrial Fatigue Research Board, the Illumination Research Committee of the Department of Scientific and Industrial Research, the National Illumination Committee, and the Illuminating Engineering Society.

The problems of illumination are very varied and have points of contact with many branches of engineering and science, so that we have been witnessing in the last few years the appearance of a new specialist—the illuminating engineer. Two of the foremost of these specialists are responsible for the work under review, in which they "have put forward the essentials of good lighting practice, have advocated those which should be adopted and have pointed out errors which should be avoided." Their first chapters deal with the eye, vision, colour and general principles, and are perhaps not so satisfactory as the rest of the book. Then follow chapters on industrial lighting, shop-window lighting—which is very well done—followed by an extensive treatment of street lighting. Motor-car headlight illumination is then dealt with, but is rather disappointing in its brevity, only one type of anti-glare device being mentioned. Chapters are devoted to flood lighting, domestic lighting, the lighting of public buildings, theatres, etc., electric signs, stage lighting, and train lighting, on all of which the authors have useful information and suggestions to communicate.

In the main the authors have accomplished their task in a very creditable fashion. The treatment is at times, however, inclined to be dogmatic even on matters of taste. For example, the authors are very fond of referring to the correct lighting or the correct type of fitting, whereas illumination problems, like quadratic equations, have more than one solution.

Much important data for the illuminating engineer are given in the form of tables, and several B.E.S.A. specifications of illumination materials are quoted in full. With regard to the tables, no attempt seems to be made to explain the application of some of them in practice; the tables of coefficients of utilisation appear as it were spontaneously, and the important depreciation factor is not explained either in the tables or in the glossary, though it is perhaps defined by implication on p. 267.

The work represents to a large extent the valuable personal experience of the authors, who have a penchant for the more luxurious and artistic aspects of the various problems with which they deal. Indeed, as the chief illuminating engineers of two important electrical companies, their experience of ambitious illuminating engineering schemes is probably unique. The average illuminating engineer has usually to treat his subjects (and his clients) in a more modest manner.

The illustrations, of which there are about 360, are a very valuable portion of the book, which is exceedingly well produced. The quality of the illustrations accounts for the apparent high price of the book, which is well worthy of study by architects as well as by all illuminating engineers.

Chinese Art and Handicraft.

Chinese Art. One hundred Plates in colour reproducing Pottery and Porcelain of all Periods, Jades, Lacquer, Paintings, Bronzes, Furniture, etc. Introduced by an Outline Sketch of Chinese Art by R. L. Hobson. Pp. 15 + 100 plates. (London: Ernest Benn, Ltd., 1927.) 30*s.* net.

THOUGH the splendid, well-nigh perfect, illustrations displayed in the one hundred colour plates of this volume may provide its most attractive feature for the general reader, all who desire to possess a clear and tersely written account of the progressive development of Chinese art, in many of its most important manifestations—valuable not only in themselves but also for their world-wide influence on the work of the artists and craftsmen of other nations—will appreciate Mr. Hobson's narrative, which forms the fitting prelude to the work; especially since his extensive knowledge of the subject matter has not overwhelmed his power of presenting the reader with a lucid and arresting narrative. The entire essay is, indeed, excellent; alike in its appreciative, yet judicial, tone and poise as well as in the selective power displayed in the marshalling of all the salient historic and cultural evidence in a brief précis which he modestly entitles an "Outline Sketch of Chinese Art." Were all descriptive accounts of national or racial achievements in art and handicraft written with such sympathy and understanding, the path of the student who is at the same time a collector, even on a modest scale, would become at once, more pleasant as well as better garnished.

In striving to select an illustrative example of the spirit with which this essay is suffused, we cannot do better than extract a few sentences from the first page of the introduction:

> "Another impression which recent discoveries have profoundly modified is that Chinese Art developed behind closed doors, unaffected by the doings of the outer world. It is now clear that in the greatest periods of her history China not only admitted, but welcomed, influences from Western and Central Asia—Scytho-Siberian, Hellenistic, Byzantine, Persian and Indian—and that, if in later times she suffered periods of virtual isolation, she was ready enough to experiment even with European art when she made its acquaintance in the seventeenth and eighteenth centuries. . . . So that during the years when her art traditions were being formed she was absorbing outside influences, and in many ways the art of the T'ang dynasty speaks in a language more intelligible to the European of to-day than does the more modern art which we have been taught to regard as typically Chinese."

The book is so profusely and admirably illustrated that every reader will feel impelled to turn again and yet again to an examination of the plates. The examples selected are, almost without exception, absolutely exemplary in their class; while, in addition to the specimens of pottery and porcelain, which seem naturally to appeal from the first onset to anyone who attempts to survey the vast panorama displayed by the artistic activities of the Chinese races throughout their long history, there are numerous beautiful reproductions of some of their magnificent achievements in painting (note the superb painting of "The Ch'ang Lo Palace, after Li Ssŭ-hsün," now in the British Museum); and in lacquer, of which Mr. Hobson has selected a series of notable and beautiful examples. Of this class the reader's attention may be specially directed to the reproduction given on Plate lxxxviii. of one panel from a twelve-fold screen now in the Victoria and Albert Museum, and to that on Plate xciii., which gives a wonderful presentation of an oblong panel in carved red lacquer encrusted with jade, malachite, and imitation lapis-lazuli. The bronze covered-pail for sacrificial wine, dating from the Chou dynasty (1122–255 B.C.), now in the famous collection of Mr. Eumorfopoulos, as well as the bronze cover of a lady's toilet-box decorated with painted designs of the T'ang period and the bronze mirror-back with designs in low-relief, also of the T'ang period and from the same collection, are beautifully rendered on a series of plates. The T'ang dynasty dish in translucent green jade from the Alexander collection, as notable for its exquisite form as for its precious colour, Plate lxxx.; the vase in translucent jade from the time of the Sung dynasty from the Malcolm collection, Plate lxxxi.; and the brush-pot in jadeite, possibly of the Yüan dynasty, are enough to make any collector's mouth water.

William Burton.

Hondius's Map of the World.

Reproductions of Early Engraved Maps. 1: *The Map of the World on Mercator's Projection*, by Jodocus Hondius, Amsterdam, 1608. From the Unique Copy in the Collection of the Royal Geographical Society, with a Memoir by Edward Heawood. On 25 Sheets, and Index Sheet, 20 in. × 15 in., in paper cover. Memoir, pp. 24. (London: Royal Geographical Society; Edward Stanford, Ltd., 1927.) 63*s*.

THIS magnificent work, the first part of a projected series of reproductions of early engraved maps, will be welcomed by all historians of geography. The original map was acquired by the Royal Geographical Society in 1919. It is in twelve main sheets, each about 18½ inches by 13½ inches, surrounded by smaller sheets containing the title and decorative borders. Though the coloured boundaries and decorations are faded, and the paper darkened with age, most of the engraving is clear, and the collotype plates render its details faithfully; even on the reduced photograph of the whole map much of the lettering is legible.

Though Hondius's map is just a century later than the first-printed world map by Waldseemüller (1507), and though Mercator's copperplate in 1569 had popularised this kind of map—as the woodcut edition of it shows—its nearer precursors were on other projections, cylindrical and stereographic; and Hondius himself reverted to a projection in hemispheres in 1611–18. His own earlier maps (1588–91) and the globes in the Middle Temple Library (1592) seem to have been engraved in England; but he appears at Amsterdam in 1593, and worked there until his death in February 1612. Full details of his copious publications, and descriptions of those which are extant, will be found in Mr. Heawood's learned introduction to this facsimile; they give a striking illustration of the interplay of English and Netherland cartographers at this time.

The quaint custom of filling the waste spaces of ocean with letterpress gives to this map a double interest for geographers; for Hondius used this opportunity to expound Mercator's projection and illustrate his own graphic method of constructing the scale of latitude, thus avoiding the necessity of further reference to his former associate, Edward Wright, who had quarrelled with him for what Wright considered premature use of his own calculations. In other matters Hondius himself had less to contribute, either to Mercator in the uses of the map, to Plancius in its details, or to Blaeu in its decorations; on the other hand, some of his novelties are attributable to English sources—Drake for north-west America, Raleigh for Virginia and Guiana. Though he restores to the map the continental land south of Magellan's Strait, which he had broken in 1602 into islands "discovered by the English," he omitted the Arctic island-world imagined by Mercator, and so both cleared the way for later explorers and stimulated their zeal.

To his expert aid in appreciating the peculiarities of the map itself, Mr. Heawood has added the convenience of a translation of its quaint Latin letterpress, with its candid admission (for example) "that no space should be left vacant, we have appended the distribution of the Sons of Noah, that it may be manifest how the World began to be settled after the flood, and from what centres colonies were first sent out into other shores"; though Hondius has to admit that it is quite uncertain who was the father of America. It is interesting to note that in his allegorical group he gives two separate figures for the Americas—one in the background of his Asia, the other of his Europe and Africa—and in the letterpress contemplates European as well as Asiatic origin for American peoples. This is a more ingenuous device than the fourfold symbolism of the title-pages of the next generation—Grimston, Heylin, and their contemporaries.

J. L. M.

Our Bookshelf.

Primitive Culture and Customs.

Maya Cities: a Record of Exploration and Adventure in Middle America. By Thomas Gann. Pp. 256 + 32 plates. (London: Gerald Duckworth and Co., Ltd., 1927.) 21*s.* net.

DR. GANN'S account of his explorations in the season 1926–27 has no sensational discovery to record such as he has given us in previous volumes. It is not on that account lacking in interest. Travel in the forests of Central America could scarcely fail to provide some thrill, either by way of fresh discovery or of personal danger. Dr. Gann experienced both. He covered both new ground and old. His most important discovery he himself considers to be the series of lofty narrow-roomed temples to the west of Bacalar Lagoon, which he had named Tzibanchè; but his discovery of a ruined city, where a mound only was thought to exist, on the site he names Minanhā, seems likely to afford an even more fruitful field for future exploration. On the sites already known which he visited, he worked at Tuluum, Uaxactun, where there is the earliest and the longest series of Maya Old Empire dates, and Lubaantun, the site now being explored by the British Museum expedition. He also visited Tikal in search of a treasure temple of which the existence was revealed to an Englishman by Indians more than sixty years ago. He was unsuccessful in his search; but his determination to make it the objective of his next journey leaves his readers with a thrill in anticipation of his next book.

The Fellāhīn of Upper Egypt: their Religious, Social, and Industrial Life To-day, with special reference to Survivals from Ancient Times. By Winifred S. Blackman. Pp. 331. (London, Bombay and Sydney: George G. Harrap and Co., Ltd., 1927.) 15*s.* net.

FOR six seasons Miss Blackman has spent six months at a time living in intimate contact with the Fellāhīn of Upper Egypt. In this volume she gives a popular account of a part only of the information she has collected about their customs, culture, and beliefs. It is extraordinarily interesting, especially when she is dealing with customs relating to childbirth and fertility and the observances and practices of the village medicine man and woman. A curious combination of offensive and defensive magic is seen in the practice of cutting out human figures in paper, sticking pins in them, and then burning them as a cure for children suffering from the effects of the evil eye. The chapter on ancient Egyptian analogies, again part only of the author's material, indicates the value of such studies as these to the Egyptologist in providing material which may serve to elucidate obscure points in his own special field. It is to be hoped that Miss Blackman may be able to continue her studies and extend them to Lower Egypt.

Papers on the Ethnology and Archæology of the Malay Peninsula. By Ivor H. N. Evans. Pp. x + 164 + 43 plates. (Cambridge: At the University Press, 1927.) 15*s.* net.

THE papers which Mr. Evans has here republished, after most have appeared in various scientific periodicals, are classified into four sections: Pagan races, Malay beliefs, Malay and other technology, and archæology. Some are of rather a specialist interest, but all are important in varying degree, for the most part as pieces of first-hand observation. Mr. Evans has been fortunate enough to visit some of the Negrito tribes of Siam and has obtained linguistic and cultural material which, though slight, is still of considerable value for comparative purposes. The section on archæology contains additions to our knowledge of the early inhabitants of the Peninsula, especially in regard to bronze and iron; but the most instructive chapter here deals with the exploration of cave shelters, in which Mr. Evans finds a culture showing a considerable correspondence with that in the rock shelters of Indo-China and exemplified in the type of primitive implement found in Sumatra by Dr. P. van Callenfels.

Experimental Psychology.

Elementary Conditions of Human Variability: a Study of the Variation of Successive Responses to Similar Stimuli at Different Levels of the Cerebro-Spinal System of a Human Subject. By Prof. Raymond Dodge. (Columbia University in the City of New York. Publication No. 10 of the Ernest Kempton Adams Fund for Physical Research, established Dec. 17, 1904.) Pp. xii + 107. (New York: Columbia University Press, 1927.) 1.50 dollars.

THIS, the tenth monograph published by the Adams Fund for Physical Research, unlike its predecessors, which came from the pens of workers in physical science, is written by a psychologist. The subject matter, however, has a direct appeal to the physicist, since it deals with that shortcoming of the individual observer from the ideal which has long passed under the term of 'personal equation,' a factor which varies from observer to observer, and in the same observer from moment to moment. The present monograph gives a quantitative analysis of the changes occurring in certain selected human reactions, *e.g.* the knee-jerk, the lid reflex to sound, horizontal vestibular nystagmus, word reactions and memory tests, all of which permit of a trustworthy technique in their recording.

From a series of observations taken at various times throughout the day and extending over a period of two years, certain types of variation in the responses become evident; *e.g.* diurnal rhythm and general depressions, to mention only two of interest in industry as regards efficiency and incidence of accidents. The effects of repetition on motor co-ordinations, the development of refractoriness, the course, transfer, and loss of training and phenomena of the learning process indicate other interesting points which are discussed. Subjective details are presented, but the value of this contribution to psychological science rests mainly on the information obtained from the trustworthy physical methods used for recording.

The Effects of Music: a Series of Essays. Edited by Max Schoen. (International Library of Psychology, Philosophy and Scientific Method.) Pp. ix + 275. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., Inc., 1927.) 15*s.* net.

A NUMBER of investigators have collaborated in the issue of this volume, which presents, under the editorial supervision of Dr. Max Schoen, studies of the effects of music and its more or less mysterious influence upon human personality. A few are reprints, notably one by Dr. Charles S. Myers, on individual differences in listening to music (*British Journal of Psychology*). The rest are in the main chosen from among papers submitted in a competition conducted by the American Psychological Association.

The effects of vocal and instrumental music on the moods of 20,000 selected individuals were obtained by phonograph recordings. These are fully described by Dr. Schoen and Dr. Esther L. Gatewood. Such collections of data through the medium of broadcasting would doubtless be impracticable; but the suspicion arises whether not a little of the acute and varied criticism extended to the official broadcast programmes may represent the expression of moods of the character detailed by the writers. Another section, of considerable general interest, by Dr. Ida M. Hyde, studies the changes produced by contrasted musical selections on electro-cardiograms, pulse rate, systolic, diastolic, and pulse pressures, and blood velocity. There is much in these essays which is of value both to professional teachers and to students of music.

Medical Manuals.

(1) *Sunshine and Health.* By Dr. Ronald Campbell Macfie. (Home University Library of Modern Knowledge.) Pp. 256. (London: Williams and Norgate, Ltd. [Thornton Butterworth, Ltd.]; New York: Henry Holt and Co, 1927.) 2*s.* net.

(2) *Clinical Application of Sunlight and Artificial Radiation: including their Physiological and Experimental Aspects, with Special Reference to Tuberculosis.* By Dr. Edgar Mayer. Pp. xvi + 468 + 38 plates. (London: Baillière, Tindall and Cox, 1926.) 45*s.* net.

(1) "SUNSHINE AND HEALTH" is one of the Home University Library series, and is therefore written with the object of summarising our knowledge of this subject for the benefit of the general reader. The author, Dr. Campbell Macfie, is but little concerned with therapeutics. He presents a short historical survey of man's speculations and theories of sunlight, and then proceeds to describe concisely, but with a wealth of detail, the nature and properties of radiant energy, its biological value and therapeutic uses. Radiation other than solar, and various types of lamps used in actino-therapy, receive brief reference.

Dr. Macfie is careful not to exaggerate the importance of light in evolution and growth, emphasising the fact that radiation cannot impart the vital spark to a group of molecules, however complexly arranged; its functions are stimulation, regulation, and reinforcement, in the development of living things. He points out that light, though necessary to plant life, is not an essential feature in animal physiology. He warns the reader that sunshine can play but a minor part in healthy metabolism, that man is as likely to suffer from excess of insolation as from deficiency, and that some of the results of actino-therapy might be due to other factors operating at the same time. The well-established facts, however, are by no means ignored, and full credit is given to radiant energy as a therapeutic agent in rickets, lupus, and other conditions.

(2) The volume which Dr. Edgar Mayer has written is entitled "Clinical Application of Sunlight and Artificial Radiation," but it contains also a very detailed and inclusive study of the biological, physiological, bactericidal, and experimental aspects of the subject, with an extensive bibliography and a complete index of authors and subjects.

Although actino-therapy is considered mainly in its application to tuberculosis, the survey of radiation in its other aspects could not be more comprehensive. The value of this book lies not only in its complete presentation of the subject. So rapid has been the development of the use of light as a therapeutic agent that the medical profession has been left somewhat bewildered, while unqualified practitioners and fascinated laymen apply ultra-violet rays indiscriminately. It must be remembered that the subject is still in its infancy; harmful effects of the application of actinic energy have been noted, and the tragedies of pioneer X-ray workers are still in our minds. Only by careful observation and cautious scientific investigation can this form of energy be made a useful agent in the struggle against disease.

The Principles of Ante-Natal and Post-Natal Child Hygiene. By Dr. W. M. Feldman. Pp. xxiv + 743 + 14 plates. (London: John Bale, Sons and Danielsson, Ltd., 1927.) 25*s.* net.

THE author intends this book as a companion to his "Principles of Ante-Natal and Post-Natal Child Physiology," child hygiene including "everything that tends to preserve the life, health and welfare of the child during its various stages of ante-natal and post-natal development." The intra-uterine development is regarded as the most important period in the child's career, and consequently the question of heredity is fully discussed, together with the relative importance of this factor and of environment when applied to child welfare and eugenics.

Three chapters are devoted to the causes and prevention of ante-natal, intra-natal, child and maternal mortality; much of this mortality is preventable, and the means available for dealing with the various factors responsible are clearly set forth. Half the total infant mortality occurs in the first month of life, and one-third on the first day; this is due to lack of adaptation in some direction to its changed environment on the part of the new-born child.

The second half of the book deals very fully with post-natal hygiene, and contains an immense amount of very practical information as to nutrition, breast feeding, artificial feeding, diet, exercise, and sunlight. The author gives not only the requirements of the child under varying conditions, but also the reasons for his statements, together with much of the experimental evidence available. The prevention of disease, both infectious and otherwise, is considered, and the book ends with chapters dealing with physical and mental growth, the psychology of the child, and adolescence.

The whole book is extremely interesting, because wherever possible the author has given the history of customs connected with the subject under discussion, and portraits of relevant investigators Many statistics are also included, and there is an excellent chapter dealing with statistical methods and the pitfalls to be avoided. E. E. Hewer.

Local Immunization: Specific Dressings. By Prof. A. Besredka. Edited and translated by Dr. Harry Plotz. Pp. xi + 181. (London: Baillière, Tindall and Cox, 1927.) 16s. net.

This small but unduly costly book is a translation, with some additions and emendations by a fellow-worker, of Prof. Besredka's "Immunisation locale," published in 1925 (Masson et Cie). According to Besredka, the production of immunity to various infective organisms is best achieved by bringing to bear on the cells most receptive for the specific micro-organism, either the micro-organism itself or a filtrate of its growth, the final issue being a desensitisation of these receptive cells so that a further inoculation of germs is rendered inert. In anthrax infection the author believes that the guinea-pig skin is the only receptive tissue in that animal, while in enteric fevers the cells which require desensitisation are those of the intestinal mucous membrane. In the latter disease immunisation is produced by oral administration of the killed organism in association with bile, which is held to facilitate, by its catarrhal action on cells of the intestinal mucosa, the impression of the specific oral antigen on these receptive cells, with resulting desensitisation. These examples of local immunity are, in the author's view, not accompanied by any very marked development of antibodies demonstrable in the blood serum.

Both the experiments and the interpretation put upon them by Besredka and his pupils have given rise to considerable controversy, and it may be stated that the great majority of workers who have entered this field of research have not reached conclusions in agreement with Besredka's particular theory. None the less, the subject of local immunity is one of intense interest, and Besredka has done good service in raising the issue, as it has directed attention to many peculiarities in local defence mechanisms, particularly in the skin, and to the bearing of quite non-specific inflammatory processes on local defence.

Actions and Uses of the Salicylates and Cinchophen in Medicine. By Prof P. J Hanzlik. (Medicine Monographs, Vol. 9.) Pp. xiii + 200. (Baltimore, Md.: Williams and Wilkins Co., London: Baillière, Tindall and Cox, 1927.) 16s. net.

The salicylates are among the most commonly used drugs and are administered in a wide range of morbid conditions. they are freely advertised to the public and somewhat recklessly taken for many transient ailments in which a physician is not consulted. They have received extensive investigation in the laboratories of pharmacologists and bio-chemists. Yet there is by no means complete understanding of their effects. and much controversy has centred round their mode of action. Recent work, however, has done much to rid these drugs of erroneous traditions which have been handed down with their use, and Prof. Hanzlik's monograph is of considerable value in summarising research and indicating present views on the subject.

Among the more important conclusions are the facts that salicylates are not specific for acute rheumatism, and that their good effects in this disease appear to be due mainly to their antipyretic and analgesic action, allowing comfort and rest. Most doctors prescribe sodium bicarbonate with salicylates with the intention of avoiding toxic effects, but there seems to be little trustworthy evidence that alkalis prevent salicysm; their main use is to counteract gastric irritation. The metabolic influence of salicylates and cinchophen—which is better known in Great Britain as 'atophan'—is fully described, but the therapeutic value must depend on a fuller understanding of morbid metabolism. Considerable prominence has been given to cinchophen during the last few years in advertisements and medical literature, and it should be emphasised that idiosyncrasy to this compound is by no means rare, and very unpleasant effects have followed its use in medicinal doses.

Prof. Hanzlik discusses many interesting features, and his book will certainly be of value, not only to physicians who use these drugs, but also to pharmacologists and others who are specially concerned with them

Manual of Psychiatry. Edited by Dr. Aaron J. Rosanoff. Sixth edition, revised, enlarged, and illustrated. Pp xvi + 697. (New York: John Wiley and Sons, Inc.: London: Chapman and Hall, Ltd, 1927) 30s. net.

This well-known text-book maintains the high standard set in previous editions The chapters on the personality and on word associations and their application are particularly welcome in a text-book of this nature.

In discussing the presence of spirochætes in the brain in general paralysis, no mention is made of the excellent work of Jahnel during the past few years, and the illustrations showing spirochætes in the brain are poor. The treatment of general paralysis is considered in a very brief manner; a chapter might well have been devoted to this, one of the most interesting and fruitful subjects in modern psychiatry. Malarial treatment is dismissed in nine lines! The author appears to consider that the high temperature of the malarial attacks is the curative factor—this is not the commonly accepted theory. There is also no mention of the use of hexamine in the prevention of paretic convulsions. Under the etiology of dementia præcox we find no mention of Mott's well-known work. Kretschmer's recent contributions on the relation of physique and character to syntonic and schizoid states and to manic-depressive insanity and schizophrenia are not even mentioned.

Notwithstanding these faults, the manual ought to be in the hands of every alienist.

Modern Methods in the Diagnosis and Treatment of Renal Disease. By Prof. Hugh MacLean. (Modern Medical Monographs.) Third edition, revised and enlarged. Pp. viii + 135 + 4 plates. (London: Constable and Co., Ltd., 1927.) 12*s*. net.

The appearance of a third edition of Prof. Hugh MacLean's monograph on renal disease is a sure indication of the well-deserved popularity of this book. Since the first edition was published, the importance and value of renal function tests have become definitely established. Experience has shown that the methods given in former editions are sufficient and trustworthy, so that no alteration has been required in the sections dealing with investigations of kidney disease. Indeed, there is little material revision in this edition except in the chapter on treatment, which has been rewritten with full practical details. The principles of treatment are based strictly on the pathology of renal impairment and its known effects; and although therapeutic measures are considered thoroughly, and in some cases suggested tables of diets are given, it is possible to apply these principles to any given degree and type of renal disease. The simplicity of classification, and the practical way in which it is written, entitle this book to be considered one of the most valuable publications on the subject.

Bird Life.

The Baby Bird and its Problems. By W. Bickerton. Pp. xvi + 135 + 39 plates. (London: Methuen and Co., Ltd., 1927.) 10*s*. 6*d*. net.

When we had read the first chapter of this book, we admit that we put it down feeling slightly dazed by it. "The Call of Spring" may be described as an ecstasy of adjectives. Long, long sentences are but partly broken by an infinite variation of colons, semi-colons and commas, generally followed, we notice, by an 'and' or a 'but.' We have, however, read this short chapter again and have come to the conclusion that in it the author does himself gross injustice. When we came to the later chapters, which are longer and in which, therefore, the author has had more to write and less time to think, the language becomes much more simple and infinitely more interesting.

We do not suppose that the book is intended for grown-up students but it is full of information for the young, whilst the information is given in a very charming manner. Naturally, in a book of this kind, a record consisting almost entirely of the author's own observations, there are bound to be many *dicta* with which his readers will not agree. For example, he says that the stone curlew is a mountain breeder. He holds up the dove as an emblem of peace, though it is well known to possess a character for quarrelsomeness surpassed by few other birds. Again, when he comments on some of his bird problems, we are inclined to think that he sometimes reverses cause and effect. Thus, on p. 37, he says that some birds construct no nest because their young are born in an advanced stage of development, yet the converse would hold equally good. Again, he says that birds which lay white eggs have learnt to lay them in holes and burrows in the ground. Most naturalists believe that eggs have protective coloration because they are not laid in holes of trees and burrows in the ground. It is probable that primitive birds hid their eggs, as do lizards nowadays, in crevices of rocks and other places in the dark, so that white or yellowish eggs are the primitive type.

An interesting chapter is the one on "Eggs; their Qualities and Meanings," in which the author compares the size of the egg with the length of the bird, though this would have been still more valuable had he compared the weights, for we see no reason why a long-tailed small bird should lay an egg larger than a large bird with a short tail. The photographic illustrations at the end of the book are admirable and are a fitting *finale* to a book in which children may learn much and their elders may read with interest.

(1) *Realities of Bird Life: being Extracts from the Diaries of a Life-loving Naturalist.* By Edmund Selous. With an Introduction by Julian S. Huxley. Pp. xvi + 351. (London: Constable and Co., Ltd., 1927.) 14*s*. net.

(2) *The Charm of Birds.* By Viscount Grey of Fallodon. Pp. xii + 243. (London: Hodder and Stoughton, Ltd., 1927.) 12*s*. 6*d*. net.

(3) *The Heart of a Bird.* By Anthony Collett. Pp. viii + 287 + 8 plates. (London: Nisbet and Co., Ltd., 1927.) 10*s*. 6*d*. net.

These three recent books on the evergreen subject of bird life have something in common. All of them deal with field observation and are based almost wholly on personal experience. All of them are descriptive rather than analytical. Each in its own way succeeds in conveying not a little of the charm of these living things and of the pleasure to be derived from intimacy with their ways.

(1) From the point of view of scientific interest, chief place may be given to Mr. Selous, who once again enriches our knowledge of bird behaviour.

He presents his material in the form of extracts from his diaries, loosely arranged in chapters according to their principal topics. It is a very readable book, into which one may pleasurably dip at almost any point. It is also packed with valuable observational records, dealing especially with courtship behaviour among birds, an extremely interesting subject of which too little is known. For the student desirous of obtaining information on particular points, the form of the book is a disadvantage, but this can be overcome by the use of an index of unusual adequacy.

(2) Lord Grey writes with his accustomed distinction. As the respective titles indicate, his record is less objective than that of the more deliberate observer. One is more aware of the personality of the writer, and one is made to feel and to share the pleasure which watching birds has given him. Of all the aspects of bird life upon which he touches, song seems to have interested him most, and nearly half the book is given mainly to this subject. No novelty is claimed for any of the observations: the most familiar fact is stated with the simple and infectious pleasure of one who has discovered it anew for himself Nevertheless, there is much here on the subject of bird song which is not often to be found in books, even those of more ambitious aim The woodcuts by Mr. Robert Gibbings are well suited to the work.

(3) Under a not altogether happy title, Mr. Collett gives us twelve pleasing essays, each dealing with the bird life of one of the months of the year. He generalises to a greater extent than the other authors just mentioned, his method being to sum his knowledge rather than to recount his separate experiences, but it is quite evident that he has seen what he describes.

(1) *Days with the Golden Eagle* By Seton Gordon, in collaboration with his Wife. Pp. xx + 176 + 19 plates (London: Williams and Norgate, Ltd., 1927) 12*s*. 6*d*. net

(2) *The Book of the Golden Eagle* By Capt C W. R Knight Pp. xii + 296 + 33 plates. (London: Hodder and Stoughton, Ltd., 1927) 21*s*. net.

THE almost simultaneous appearance of two works on the golden eagles of Scotland suggests a comparison and contrast. The main theme of both volumes is the life-history of the eagle, from egg to adult, as it is revealed day by day to the patient watcher by the eyrie, and both stories are vivid with the personal experiences of the authors, for in bird photography interest in the doings of the photographer appears to be second only to interest in his quarry. Mr. Seton Gordon, however, devotes only about a quarter of his space to this detailed study. The remainder of his book is given over to more general themes bearing upon the golden eagle: an account of Scottish eyries, descriptions of typical eagle country, the incidence of eagles on grouse preserving and sheep farming, Highland stories and traditions of the eagle, and the history of the golden and white-tailed eagles in Britain.

Captain Knight confines his account to his own observations; it is, in short, a sprightly history of his experiences in the taking of his wonderful eagle film, and of his training of a young eagle to fly to the lure. Mr. Gordon's book is for the reader who would know almost all that is to be known about the golden eagle; Captain Knight's for him who prefers a racy story of eyrie-hunting expeditions.

Zoology in the Laboratory.

(1) *A Laboratory Course in General Zoology: a Guide to the Dissection and Comparative Study of Animals* By Prof. Henry Sherring Pratt. Pp. x + 244. (Boston, New York, Chicago and London: Ginn and Co, Ltd, 1927.) 7*s*. 6*d*. net.

(2) *The Skate* Raja erinacea *Mitchill*. *a Laboratory Manual* By Prof. Charles W. Creaser Pp. xi + 57. (New York: The Macmillan Co., 1927.) 4*s*. 6*d*. net.

(3) *The Biology of the Frog.* By Prof. Samuel J Holmes. Fourth revised edition. Pp. x + 386 (New York. The Macmillan Co., 1927.) 10*s*. 6*d*. net.

(4) *Textbook of General Zoology.* By Prof. Winterton C. Curtis and Prof Mary J Guthrie. Pp xv + 412. (New York: John Wiley and Sons, Inc., London: Chapman and Hall, Ltd, 1927.) 18*s*. 6*d*. net.

(5) *Leitfaden zu tierphysiologischen Übungen.* Von Prof Dr. Paul Kruger. Pp. viii + 92. (Berlin: Gebrüder Borntraeger, 1927) 3 gold marks.

THE output of new text-books or of new editions of old ones is as steady as the advance in scientific knowledge and advances in teaching methods. For the latter reason it is always very interesting to compare the productions of different countries and to note the trends in teaching. American text-books are usually of special interest, for they may be used by the English student (if the language used remains reasonably English) and the American publisher has the advantage of a wider sale than in his own land. Naturally, they must be of high grade. English publishers of text-books should not forget the American market, a field which is frequently less well explored by advertisement than it might be.

(1) Pratt's laboratory manual is called "General Zoology," but it is nothing of the kind unless general be taken to mean 'diffuse.' It is an extraordinary collection of elementary references to invertebrate types, only structure is mentioned and often only external characters. To this are added the frog and the perch. It is difficult to see for whom it could possibly be intended

(2) The laboratory manual on the skate is the kind of handbook which might be used as a guide to dissections of this type Such books, if they are going to be useful for the student, should be illustrated This specimen contains only two old illustrations. Its style is bad and many expressions are extraordinarily misleading.

(3) Holmes's work on the frog stands on a different plane, and is an effort to provide a complete description of the frog, including its physiology, habits, and instincts as well as structure. Much information is brought together which otherwise

only exists in scattered form. The only fault of the book is that it remains clearly a new edition of an old work, many chapters of which have needed considerable revision. Here and there the revision is still not up-to-date.

(4) Curtis and Guthrie's work is another American text-book which demonstrates how usual it is in America (compared with England) to combine the study of function and structure in zoological laboratories. It is a well-written volume and, on the whole, up-to-date. The physiology is perhaps rather 'thin,' two short chapters comprising the physiology of the vertebrate type, and this is practically human physiology. On the other hand, there are many good features, and the different sections are well balanced.

(5) Kruger's little book of 92 pages (costing 3 marks in Germany) is very interesting, for it shows that zoology students in Berlin have a short practical course in animal physiology. The book is a student's guide to this laboratory work. It is mainly a collection of bio-chemical tests and is extracted from a larger volume by the same author. It must be a very useful manual to German students.

Handbuch der Zoologie: eine Naturgeschichte der Stamme des Tierreiches. Gegründet von Prof. Dr. Willy Kükenthal. Herausgegeben von Dr. Thilo Krumbach. (1) Dritter Band: *Tardigrada; Pentastomida; Myzostomida; Arthropoda, Allgemeines; Crustacea; Arachnoidea.* Sechste Lieferung. Pp. 593-720 Siebente Lieferung. Pp. 721-848. Achte Lieferung. Pp. 849-976. Neunte Lieferung. Pp. 977-1158 + xvi. (2) Siebenter Band: *Sauropsida, Allgemeines; Reptilia; Aves.* Zweite Hälfte, Erste Lieferung. Pp. 112. Zweite Lieferung. Pp. 113-224. (Berlin und Leipzig: Walter de Gruyter und Co., 1927.)

(1) THE sixth, seventh, eighth, and ninth parts of the third volume of this handbook contain the descriptions of the rest of the orders of Crustacea—Anaspidacea, by Dr. P. A. Chappius, Mysidacea, Cumacea, Tanaidacea, Isopoda, and Euphausiacea, by Prof. Carl Zimmer, Amphipoda by Prof. J. Reibisch, and Decapoda and Stomatopoda by Prof. H. Balss. Under each order is found an account of the structure (usually with adequate references to physiology), distribution, life-history, ecology, and classification, with a list of the more important memoirs. Numerous figures from recent papers are included. Three pages have been added in order to include a summary of the results of the observations of Prof. Graham Cannon and Miss Manton (1927) on the feeding of Hemimysis. The account of the Crustacea extends to 800 pages. The figures of larval forms of the Decapoda should have included better representations of the internal anatomy, which is too much neglected even in the Phyllosoma larva, where the internal structure could have been well shown.

The contributions to this volume maintain a high standard, and the articles will be of great service to teachers of zoology and to advanced students. The volume is provided with an excellent index.

(2) In these two parts Dr. E. Stresemann deals with the external features of birds, the structure and arrangement of feathers, coloration, skeleton, musculature, nervous system, and sense organs, and the digestive, respiratory, and vascular systems. The microscopic structure of the more important organs and their physiology receive careful attention. The account is well illustrated, and a large proportion of the figures is from recent memoirs. The author is successfully handling a difficult subject, and his volume on birds promises to be a very helpful and up-to-date part of the 'Handbuch.'

Sagitta. By S. T. Burfield. (Liverpool Marine Biology Committee Memoirs on Typical British Marine Plants and Animals, edited by Dr. James Johnstone, 28.) Pp. viii + 104 + 12 plates. (Liverpool: University Press of Liverpool, Ltd.; London: Hodder and Stoughton, Ltd., 1927.) 6*s*. 6*d*.

THIS latest addition to an excellent series of memoirs will be welcomed by all zoologists, especially by senior honours students. *Sagitta bipunctata* Quoy and Gaimard, or the 'arrow-worm' as it is appropriately termed in common speech, is a well-known and important member of the marine plankton and has frequently been studied, from both the morphological and ecological aspects, by workers on both sides of the Atlantic. This book is a detailed account of the anatomy and minute histology of this living slip of transparency, and the author has included sections in which what is known of the affinities, occurrence, habits, vertical distribution, and parasites are briefly discussed. Gametogenesis and development also receive attention. The whole is illustrated by more than a hundred line-drawings and diagrams, but one feels that some of these would have been more effective had they been reproduced on a rather larger scale. Probably space-saving considerations precluded this possibility. The preparation of the memoir has obviously entailed a great deal of work, and the author is to be congratulated on its successful accomplishment.

Recent Advances in Anatomy. By Prof. H. Woollard. (The Recent Advances Series.) Pp. vii + 302 + 4 plates. (London: J. and A. Churchill, 1927.) 12*s*. 6*d*.

PROF. WOOLLARD has written a very stimulating sketch of some of the progressive movements in anatomy, which gives an idea of the wider vision that is now opening out in this hoary subject. He has not attempted, however, to deal with the whole range of anatomical progress, but has discussed only these topics of which his associations in America, in Holland, and at University College, London, have given him a personal knowledge and interest. The vitalising influence of the functional point of view is everywhere apparent in the wide range of topics, neurological, cytological, and embryological, he has thus selected;

and the book will exert a healthy influence in emphasising the expression of this principle in the growing points in anatomy.

The chief criticism is that the author has crowded into a limited space an amazing amount of detailed and novel information without including enough of the older knowledge to link on the new data. Hence he is not easy to follow and understand. When the time comes for preparing a new edition of this work—which is so useful that the occasion should not be delayed very long—the author ought to make a drastic revision, not merely to correct the typographical errors and the too numerous ambiguities, but also to prune the list of facts, so as to give more room for interpretation

Natural History of Insects.

Mosquito Surveys: a Handbook for Anti-Malarial and Anti-Mosquito Field Workers. By Malcolm E. Macgregor. (Published for the Wellcome Bureau of Scientific Research) Pp. 293. (London: Baillière, Tindall and Cox, 1927) 15*s.* net.

In 1922 the author was sent to Mauritius on behalf of the Colonial Office to make a thorough study of malaria, and he has prepared this account of the mosquitoes of that island and of Rodriguez primarily for the information of the Medical and Health Department. The first part forms a clear and concise introduction to mosquito anatomy and life-history which the author is well qualified to provide, but "trochanta," "pleuræ," and "collecterial" are surely due to slips of the pen. The statement that the spermathecæ are usually three in number requires further qualification. There are said to be (p 50) two diverticula of the œsophagus, whereas three, the correct number, are indicated in the figure and given on p 219 The method suggested for determining the sex of the pupa is "by the presence or absence of rudimentary testes," but a quicker determination can usually be made by examining the processes in which the external genital armature is developing.

The second part is devoted to the classification of mosquitoes and to a useful account of the four species of Anopheles found in Mauritius—the genus is absent from Rodriguez—and of the Culicines found in both islands. Keys are given to aid in the identification of the larvæ and adult insects It is doubtful whether the key to the Culicine genera of the world should have been included, for its use requires considerable expert knowledge not likely to be possessed by those for whom the book is primarily intended.

The third part contains many helpful suggestions for work in the field and in the laboratory, for example, a device for keeping creosote in small glass bulbs in insect store-boxes, methods of mounting mosquitoes on celluloid strips, the rearing of larvæ in captivity, and the mounting of parts of larvæ, pupæ, and adults as microscopic specimens. Ten pages are devoted to suggestions for anti-malaria and anti-mosquito surveys and for mosquito control.

The Plant Lice or Aphididæ of Great Britain By Fred V Theobald. Vol. 2 Pp. v + 411 (Ashford, Kent, and London. Headley Bros, 1927.) 30*s*

Entomologists will welcome the appearance of the second volume of Mr Theobald's invaluable book on the British aphides. This volume follows on the same lines as the previous one. It deals with the remaining genera and species of the tribe Aphidini, and in addition certain members of the tribe Callipterini Altogether 26 genera and about 150 species are dealt with, and of the latter 64 and 36 respectively belong in the genus Aphis and Anuraphis. The remaining genera contain only from one to eight British species.

The labour entailed by this monumental work is evident from a study of the complex synonymy of many common species, and we are deeply indebted to the author for the way in which he has straightened out the chaotic tangle in which many important species have been struggling in the past It is clear that the habits and behaviour of many economic species vary considerably in different countries

The inevitable change of the specific name of well-known species may trouble the economic entomologist for a time. but the correct name will have the value of permanency. In this respect it is to be hoped that the type of the genus Aphis will be soon definitely agreed upon by the acceptance of the latter as a *genus conservandum*

We do not understand why *Aphidella secreticauda* Theob (gen et sp. nov 1923) should become *Aphidiella secretocauda* in the present volume, as we are not aware of any published note explaining the change and the name in its original form has already passed into the literature.

With these two volumes now available, it is evident that this authoritative work will be welcomed by entomologists, not only in Britain but also throughout the world. James Davidson.

Faune de France (Fédération française des Sociétés de Sciences naturelles. Office centrale de Faunistique.) 15: *Diptères* (*Nématocères*), *Chironomidæ, Tanypodinæ.* Par M. Goetghebuer. Pp. 83. 18 francs 17: *Diptères* (*Brachycères*). (*Asilidæ*) Par E. Séguy. Pp 191 35 francs. (Paris Paul Lechevalier, 1927.)

The appearance of volumes of the "Faune de France" series has frequently been noticed in these columns No 15, by M. Goetghebuer, of Ghent, deals with the little studied group of midges comprising the subfamily Tanypodinæ, and his account is the only comprehensive one dealing with the European forms. No. 17, by M. E. Séguy, of the Natural History Museum of Paris, is devoted to the Asilidæ or robber flies and is profusely illustrated with 384 figures His contribution is particularly interesting, as the prey of each species are listed wherever known, and there is a useful account of the metamorphoses based largely upon the recent work of Melin. Both volumes are well up to the standard of their predecessors and will unquestionably prove of real assistance to students of the British species in the groups reviewed. The Office Centrale de Faunistique concerned with the publication of those monographs is to be congratulated on their excellence and the general uniformity of treatment that is being maintained in this truly admirable series.

Thysanoures, dermaptères et orthoptères de France et de la faune européenne. Par Prof. C. Houlbert. (Encyclopédie scientifique : Bibliothèque de zoologie.) Tome 2. Pp iv + 357. (Paris : Gaston Doin et Cie, 1927.) 32 francs

THE first volume of the above work was published in 1924, and the appearance of the second completes the account of the Orthoptera. The latter are treated under two sub-orders—the Dictyoptera, which include the Blattidæ and Mantidæ, and the Eutelioptera, which embrace the remaining families. The descriptions given of the various species are concise and clear, while the numerous illustrations are useful aids to identification. These features, together with the handy pocket size of the book, should make it a serviceable companion for the field naturalist in many parts of Europe. There is a considerable bibliography at the end of the book, and most of the chief works dealing with Orthoptera are listed.

Pages of History.

Avicennæ de Congelatione et Conglutinatione Lapidum : being Sections of the Kitâb Al-Shifâ The Latin and Arabic Texts edited with an English translation of the latter and with Critical Notes. By E. J. Holmyard and D. C. Mandeville. Pp. ix + 86 (Paris : Paul Geuthner, 1927.) n p

THE authors show that the Latin treatise ' De congelatione et conglutinatione lapidum," which is printed in early alchemical books as a work of Avicenna's, is a translation of part of Avicenna's book, "The Book of the Remedy (*Kitâb al-Shifâ*)," and is therefore one of the few medieval translations from Arabic for which the original text dealing with alchemy is available. The work has been attributed to Aristotle, but is clearly a part of the treatise of Avicenna written as a commentary on Aristotle about A.D. 1022. In the Latin translation the work is divided into three parts, the last two having the titles " De causa montium " and " De quatuor speciebus mineralium." The work contains some very interesting geological speculations on the formation of stone, rock, and mountains, on the nature of minerals, and an adverse criticism of the alchemists. The authors consider that it probably represents opinions arrived at by Avicenna late in life, and that at an earlier period he probably composed books in favour of alchemy.

It is interesting to see these Latin translations of Arabic works, until a short time ago airily dismissed as ' forgeries,' brought into relation with their authentic originals, and we may hope that before long others may be added to the list. Messrs. Holmyard and Mandeville have made a very interesting and useful contribution to the history of chemistry.

An Introduction to the Study of Experimental Medicine. By Claude Bernard. Translated by Henry Copley Greene With an Introduction by Prof. Lawrence J. Henderson. Pp. xxi + 226. (New York : The Macmillan Co., 1927) 12*s.* 6*d.* net.

STRIKING evidence of the growing interest in the history of medical science is furnished by the recent appearance of this translation of the great French physiologist's classical work, which was first published more than sixty years ago. The translation is preceded by an introduction by Lawrence J. Henderson, professor of biological chemistry at Harvard University, who attributes the insufficient recognition which Bernard's writings have received to their having been overshadowed by the growth of bacteriological research. The introduction is followed by a translation of an appreciation of Claude Bernard by Paul Bert, who was his favourite pupil and successor at the Sorbonne.

Bernard's work consists of three parts. In the first, which deals with experimental reasoning, he emphasises the importance of the experimenter being at once a theorist and a practitioner, and maintains that physiological and pathological states are controlled by the same forces but differ only because of the special conditions under which the vital laws manifest themselves. In the second part, which is devoted to experimentation on living beings, the case for vivisection is luminously set forth. The third part contains applications of the experimental method to the study of vital phenomena, as illustrated by Bernard's own investigations.

The translator is to be congratulated on his excellent rendering of the French text.

School Science.

Readable School Biology. By O. H. Latter. (Bell's Natural Science Series.) Pp. xii + 143. (London : G. Bell and Sons, Ltd., 1927.) 2*s.* 6*d.*

THE publishers are to be congratulated upon the production of what should prove a popular addition to their Science Series, and the veteran naturalist and science master of Charterhouse upon the astounding range of biological fact and theory which he has concentrated into less than 150 pages. Well printed and containing 48 figures (many of them original), the book is very good value for money. The author has struck the distinctively modern note in biological teaching by emphasising the physiological aspect of his subject ; so that the general reader will not be tired by tedious descriptions of types or by long lists of unfamiliar names. There is, indeed, a section on ' classification ' ; but here the reader is directed to general principles, the evolutionary scale, and the mind is left with an impression of living organisms rather than of museum specimens in jars correctly labelled.

The endeavour to live up to the title " Readable " has inveigled the author into some rather strained anthropomorphic analogies ; that on p. 136 is particularly unfortunate in that it gives entirely erroneous conceptions both of the behaviour of the chromosomes during meiosis and of their relation to inheritance. A number of Mr. Latter's colleagues will not be disposed to accept his assertion that "with classes taking Biology as part of their *general education*, personal practical work by the pupils themselves is sheer waste of time and money"; this need not, however, prevent even such from using his book, which is eminently readable.

Elementary General Science. By J. B. Jenkins. (Bell's Natural Science Series.) First Year's Course. Pp. viii + 149. Second Year's Course. Pp. vii + 171. (London: G. Bell and Sons, Ltd., 1927.) 2*s.* each.

THE arrangement of the subject matter of this introduction to physics and chemistry is unusual. Each volume is divided into three parts. In the first, very full instructions are given for carrying out a series of experiments, and each experiment is followed by a list of questions to assist the pupil to make the correct observations and inferences. In the second, the results of each experiment are discussed, and the third deals with the applications of the facts acquired.

Part I. is reminiscent of a cookery book, and it is disappointing to find that right to the end of the two years' course it is necessary to ask a question to ensure an observation or an inference. "Is the test-tube still intact?" follows the bursting of a test-tube by filling it with water and freezing the water! The electric bell would afford a valuable lesson but for the diagram and explanation, which 'give the show away.' Many of the experiments are more suitable for demonstration than for individual work.

There is something to be said for separating Parts II. and III., as a pupil frequently remembers the application but forgets the fact or principle, because the former made a vivid impression before the latter had been grasped.

Smith's Inorganic Chemistry. Revised and rewritten by Prof. James Kendall. Pp. xxvi + 1030 + 15 plates. (London: G. Bell and Sons, Ltd., 1927.) 12*s.* 6*d.* net.

IN this new edition of a well-known text-book, Prof. Kendall has been able to preserve the general plan and spirit of the original and at the same time to incorporate a considerable amount of new material. Of the many new topics dealt with, special mention may be made of the new views on the ionisation of strong electrolytes, which are very skilfully explained in simple language. The book is one of very modern conception and gives an excellent account of the elements of inorganic chemistry, with sections on physical chemistry and the organic chemistry of everyday life.

Elements of Chemistry. By Prof Harry N. Holmes and Louis W. Mattern. Pp. xi + 519. (New York. The Macmillan Co., 1927.) 7*s.* 6*d.* net.

HOLMES and Mattern's book is chiefly noteworthy for the many excellent illustrations of chemistry in its applications to industry and daily life. There are more than 250 illustrations, many of them from photographs, and they certainly convey a most vivid picture of the ramifications of chemistry in all parts of modern life. For this feature alone the book is well worth inclusion in a school library. The text contains many references of interest to industrial processes, and teachers of elementary chemistry should find the book useful and stimulating.

Classified Problems in Physics. Part 1: *Mechanics and Hydrostatics.* By Dennis Brook Briggs and M. Briggs. Pp. viii + 128. 3*s.* Part 2: *Magnetism and Electricity.* By Dennis Brook Briggs. Pp. viii + 128. 3*s.* Part 3: *Heat, Light, and Sound* By Dennis Brook Briggs. Pp. viii + 183. 3*s.* 6*d.* (London: Sidgwick and Jackson, Ltd., 1928.)

IN addition to some hundreds of problems, mostly numerical, of the standard of the school certificate examination, these books contain definitions, proofs of formulæ, and worked examples. The purpose they serve is difficult to see. They are not text-books, and as supplements they are, or should be, unnecessary. The pupil who solves more than a small fraction of the problems is learning arithmetic rather than physics. The teacher might find the problems useful, but would not need the other portions of the book.

Miscellany.

Coal in Great Britain: the Composition, Structure, and Resources of the Coalfields, Visible and Concealed, of Great Britain. By Dr. Walcot Gibson. Revised and enlarged edition. Pp. viii + 334 + 8 plates. (London: Edward Arnold and Co., 1927.) 21*s.* net.

THE fact that a new edition of Dr. Walcot Gibson's well-known book "Coal in Great Britain" has been called for seven years after the original publication of the book is evidence that the work has filled, and has filled satisfactorily, a want in coal mining literature. The new edition follows quite closely the arrangement of the previous one, but some of the material in the first edition has been expanded, so that the new volume contains 334 pages as against 311 in the earlier edition. A brief chapter has been added on the origin and composition of British coalfields; the chapters dealing with the coalfields of North Staffordshire, Yorkshire, and Nottinghamshire have been somewhat enlarged, and have been brought up-to-date by the light of recent investigations. This is perhaps particularly true of the great Yorkshire, Nottinghamshire, and Derbyshire coalfield, where development has been proceeding very actively during recent years, although there is still room for much investigation, seeing that the author himself admits that "the northern, eastern, and southern productive limits of the concealed basin remain conjectural." Full advantage has been taken of recent publications on the coalfields of Scotland, although these are still dealt with in one chapter, whereas the material available would readily have warranted a considerably more extended description. Perhaps the most disappointing chapter in the book is that dealing with the

East Kent coalfield, in the description of which advantage does not appear to have been taken of the most recent information. The new edition remains, however, as was the first, the best brief comprehensive survey that we possess of the coalfields of Great Britain.

Wireless Direction Finding and Directional Reception. By R. Keen. Second and enlarged edition. Pp. vii + 490. (London: Iliffe and Sons, Ltd., 1927.) 21*s.* net.

THIS work was first published in 1922 under the title "Direction and Position Finding by Wireless." In the interval, the wireless direction-finder, both in its application to navigation and as a useful instrument for scientific research, has developed to a considerable extent; and it is not surprising, therefore, to find that a second edition of Mr. Keen's book has been called for. The book has been revised in a thorough manner and considerably enlarged, while its scope has been usefully extended to include directional reception for communication purposes.

The earlier chapters deal in a clear and simple manner with the fundamental theory of directional receiving aerials, whether of the closed loop type used in direction-finding, or the extended open type used for beam communication. A description is then given of the various practical types of direction-finder used for aerial and marine navigation, and in the case of the Bellini-Tosi system, detailed working instructions are given for the choice of site, erection and calibration of the direction-finder on ship or shore. The navigational side of the subject is dealt with in three chapters, containing details of the special maps and charts which are required and the necessary instruction in field and nautical astronomy. Modern research is summarised in a chapter on the phenomena of night errors and coastal refraction, and the relation of these to the propagation of electromagnetic waves is explained.

A most valuable portion of the book is the bibliography of 374 references, which have been well chosen and are arranged chronologically in an excellent manner. The book is well illustrated by a large number of diagrams and photographs, and the production leaves nothing to be desired. It should undoubtedly be in the possession of everyone interested in the subject of directional wireless.

R. L. SMITH-ROSE.

A Survey of the Social Structure of England and Wales: as Illustrated by Statistics. By A. M. Carr-Saunders and D. Caradog Jones. Pp. xvii + 246. (London: Oxford University Press, 1927.) 10*s.* net.

THE compilation of accurate statistical data for public edification is a twentieth-century phenomenon. It is a logical outcome of the demand of the reasonable for facts upon which to base action and opinion. The facts which have emerged have been of incalculable assistance to social reformers, whose appetite has grown until at the present time a varied and abundant but somewhat indigestible fare is available for consumption. This volume is a praiseworthy effort to assist the public in its task of assimilation. It gives form and coherence to the vast accumulated mass of statistics from official and unofficial sources which bear on the various aspects of the social life of the community. Even more valuable still, it points out the existing gaps in the statistical data available.

By virtue of its presentation of facts without prejudice, the judicial calm with which the many defects in our social structure are noted and commented on, this volume can be commended to all serious students of social science. But those who expect to find prescriptive remedies for our social ills or a general social theory will be disappointed. The authors are content to give the outlines of the problems confronting society, such as those connected with the numerical preponderance of women, the effect of heredity, environment, and education on quality of population, the distribution of wealth, and the social aspect of the methods adopted by various sections of the community for the protection or improvement of their position in society. It merits the closest attention of scientific workers because of its suggestiveness and the clarity with which it blazes the trail for others in this fascinating, if perplexing, field of research. A. G. C.

Pitman's Dictionary of Industrial Administration: a Comprehensive Encyclopædia of the Organisation, Administration, and Management of Modern Industry. Edited by John Lee. Complete in about 30 fortnightly Parts. Part 1. Pp. xv + 48. (London: Sir Isaac Pitman and Sons, Ltd., 1928.) 1*s.* 3*d.* net each Part.

WITH the present trend towards amalgamation and co-operation of effort in industry with the view of improving the organisation of production and marketing effort, this work should be specially welcome to those now actually engaged in the organisation, administration, and management of modern industry, or those who hope to attain positions of importance in the future. In America and Germany nearly every industry has its authoritative work of reference; and while there are several text-books in Great Britain devoted to single aspects of the problem of scientific management, this dictionary is, so far as we are aware, the first attempt to cover the whole subject in comprehensive fashion. A reference to the first part shows that every subject and problem that are likely to arise in a well-organised undertaking are dealt with briefly, and without the over-theorising from which many similar treatises, written from the academical rather than from the practical point of view, suffer. The student and practical man will find articles on production, administration, marketing, insurance, finance, welfare, accident prevention, hygiene, transportation, power, and other aspects of the one big problem of efficient management. Unlike some other similar works, the dictionary is generously cross-referenced to enable the student to find the information he is seeking with the minimum of trouble. A really full index in the last volume should still further enhance the value of the work.

Forthcoming Books of Science.

Agriculture, Forestry, and Horticulture.

Ernest Benn, Ltd.—Agricultural Progress, edited by J. R. Bond. *A. and C. Black, Ltd.*—Black's Gardening Dictionary, edited by E. T. Ellis, new edition. *Chapman and Hall, Ltd.*—Green Manuring, A. J. Pieters; Seed Production and Marketing, J. F. Cox and G. E. Starr; Farm Soils: their Management and Fertilisation, E. L. Worthen. *W. Heffer and Sons, Ltd.* (*Cambridge*).—The Evolution and Classification of Soils, E. Ramann, translated by Dr. R. Whittles. *Longmans and Co., Ltd.*—Hundred Acre Farm, G. T. Garratt. *Macmillan and Co., Ltd.*—Elements of Quality in Cotton, Dr. W. L. Balls; Text-book of Tropical Agriculture, Sir H. A. A. Nicholls, new edition, revised by J. H. Holland. *G. P. Putnam's Sons, Ltd.*—Mushroom Book, Dr. W. S. Thomas.

Anthropology and Archæology.

Cambridge University Press.—Life in the Middle Ages, G. G. Coulton, Vol. I.: Religion, Folk-Lore, and Superstition; An Outline of the Early Civilisations of the Carpatho-Danubian Countries, Prof. Vasile Pârvan, translated by I. L. Evans; The Naron, D. F. Bleek. *Chapman and Hall, Ltd.*—Folk Tales of Provence, W. B. J. *Chatto and Windus.*—Early History of Assyria, S. Smith. *G. G. Harrap and Co., Ltd.*—Myths and Legends of the Polynesians, Prof. J. C. Andersen. *Longmans and Co., Ltd.*—Indian Culture Through the Ages, Prof. S. V. Venkateswara, Vol. I.: Education and the Propagation of Culture. *Sampson Low and Co., Ltd.*—The Story of Civilisation, H. Cory. *Macmillan and Co., Ltd.*—The Life of a South African Tribe, Dr. H. A. Junod, new edition, 2 vols.; The Palace of Minos: a comparative account of the successive stages of the Early Cretan Civilisation as illustrated by the Discoveries at Knossos, Sir Arthur Evans, Vol. 2, 2 Parts. *John Murray.*—A Short History of Civilisation, Prof. L. Thorndike; The Art of the Cave Dweller: a Study of the Earliest Artistic Activities of Man, Prof. G. Baldwin Brown; The Age of the Gods: a Study in the Origins of Culture in Prehistoric Europe and the Ancient East, C. Dawson. *Kegan Paul and Co., Ltd.*—The History of the Devil: a Study in Magic and Superstition, R. L. Thompson; The Story of Myths, E. E. Kellett; The Roman World, Prof. V. Chapot; Macedonian Imperialism, and the Hellenisation of the East, Prof. P. Jouguet. *G. Routledge and Sons, Ltd.*—Race and Civilisation, F. Hertz. *Seeley, Service and Co., Ltd.*—On the Trail of the Veiled Tuareg, D. Campbell; The Glamour of Near East Excavation, J. Baikie.

Biology.

A. and C. Black, Ltd.—The Story of the Hive: a Bee-Lover's Book, C. Williams; Creatures that Fly, A. Winifred Vaizey; Creatures that Swim, A. Winifred Vaizey. *Cambridge University Press.*—William Bateson, Naturalist, Essays and Addresses, together with a short account of his Life by Mrs. Bateson; Ciliary Movement, J. Gray (Cambridge Comparative Physiology). *Chapman and Hall, Ltd.*—Game Birds, D. Dewar; Evolution, B. C. Gruenberg; Text-book of Zoology, W. C. Curtis and Mary J. Guthrie; Introduction to Vertebrate Embryology, W. Shumway; Histological Technique, B. F. Kingsbury and O. A. Johannsen. *J. and A. Churchill.*—An Elementary Text-book of General Microbiology, W. Giltner. *J. M. Dent and Sons, Ltd.*—A Matriculation Botany, Miss Johnstone; The Ecology of Plants: or Distribution of Vegetation in the British Isles, Miss Johnstone. *Gurney and Jackson.*—Retrospect: Reminiscences and Impressions of a Hunter-Naturalist in Three Continents, 1851–1928, A. Chapman; Popular Handbook of Indian Birds, H. Whistler. *Macmillan and Co., Ltd.*—African Jungle Life, A. Radclyffe Dugmore; A Text-book of Zoology, the late Prof. T. Jeffery Parker and the late Prof. W. A. Haswell, new edition, in 2 vols., Vol. 1 revised by Dr. W. D. Lang, Vol. 2 revised by C. Forster Cooper. *G. P. Putnam's Sons, Ltd.*—The Social World of the Ants Compared with that of Man, Dr. A. Forel, translated by C. K. Ogden; Birds of the Ocean, W. B. Alexander; The Field Book of North American Mammals, H. E. Anthony. *G. Routledge and Sons, Ltd.*—The Guests of British Ants: their Habits and Life-Histories, H. St. J. K. Donisthorpe

Chemistry.

ornaments in glass paste. Finally, small beads of glass paste lying in masses show a pattern worked in colours, probably part of a garment, a new feature in Mycenæan art. Pottery dates the tomb at about 1300 B.C. No human remains were found, and Prof. Persson suggests that the tomb may have been the cenotaph of a chief. This would agree with the great attention known to have been paid to the dead by the Mycenæans and with practices suggested in several Homeric passages.

THE Boyden Station of the Harvard College Observatory, which was situated at Arequipa, Peru, from 1890 until 1927, has now been re-established near Bloemfontein in the Orange Free State. Photographic work with two telescopes was resumed in September 1927, using the temporary quarters provided by the city of Bloemfontein while the permanent station is under construction on a low kopje a short distance south of Mazel's Poort, the power station settlement of the city. Bloemfontein is providing the permanent site for the new observing station, and making roads and other improvements for the Harvard Observatory. Under the former director, Prof. E. C. Pickering, and the present director, Prof. Harlow Shapley, the Harvard Observatory has maintained for forty years a very active interest in the southern sky, and nearly one-half of the great collection of astrographic plates at Harvard were made at its Boyden Station. The observing conditions at Arequipa were excellent for about eight months of the year, but a prolonged cloudy season from November to March badly hampered the systematic observations. The cloudy weather at Bloemfontein is more evenly distributed through the year, and at the same time the transparency and seeing are extraordinarily good. The transfer of the station and its enlargement were made possible through gifts by the International Education Board and by Harvard University. A new 60-inch reflecting telescope, to be the largest instrument in operation in the southern hemisphere, is being constructed for the Boyden Station. Other instruments that will be in operation are photographic doublets of eight inches and twenty-four inches aperture, a 10-inch photographic triplet, the 13-inch Boyden refractor, and photographic cameras of one, three, and five inches aperture. The problems under investigation include extensive studies of variable stars, extra-galactic nebulæ, globular star clusters, proper motions, and spectral classification and analysis. The transfer and erection of the station are under the immediate supervision of Dr. J. S. Paraskevopoulos.

THE *Annual Report* of the Committee of Management of the Lewis Evans Collection of Scientific Instruments at Oxford has just been published. It records the restoration of the main exhibition room in the Old Ashmolean Museum to its original condition, and the unveiling by Viscount Cave, as Chancellor of the University, of the memorial windows to Dr. Plot and to Sir Christopher Wren. All the astrolabes in the collection have now been photographed in preparation for an illustrated catalogue; important memoirs on the subject of the astrolabe have been published by Dr. R. T. Gunther, the curator of the collection. Among recent accessions are a 6-in. reflecting telescope made by Sir William Herschel, and the fine silver microscope made by G. Adams for George III. The telescope has been presented by Dr. Herbert N. Evans, of Exeter College, himself a cousin of Dr. Lewis Evans; it was formerly in the possession of Archdeacon Nathaniel Jennings, who had a small private observatory on the north side of Regent's Park, London. The George III. microscope, apart from its interest as an example of the silversmith's art, admirably illustrates the advance made in one century from the instrument designed by R. Hooke, of Christ Church, in 1665. Among other accessions are a 'thunderhouse' and a frictional electric machine, both of which are associated with Joseph Priestley. The Report ends with a reference to the finances of the collection, which in spite of liberal gifts from the great City Companies and other public bodies both within and without the University, cannot yet be said to be on a satisfactory footing.

PROF. A. LABBÉ's work on copepods in the saline waters of Croisic, and his claims to have established an evolution from one genus to another, have been discussed by Mr. R. Gurney and Mr. A. G. Lowndes in the columns of NATURE (Sept. 4, Oct. 16, 1926; Aug. 27, 1927). These 'allomorphs,' or transition forms, he affirms may be produced by slight alteration in the environment, both in the laboratory or, within a longer period, naturally in the marshes themselves. Thus in eight stages, during seven years he claims to have transformed Canthocamptus into Cyclops, and similarly many forms have been changed from one genus to another. Mr. Gurney's criticisms are based, first, on the incomplete evidence given, Prof. Labbé himself admitting that his aquaria were not absolutely free from contamination by other species, and giving no exact details of his experiments so that the evidence can be weighed; and secondly, on the wrong identification of his forms, some of the new genera being apparently identical with those already known, and the figures themselves inaccurate. Mr. Lowndes attacks the problem from another quarter, questioning the results on the grounds of the impossibility of such small increases in the pH being capable of producing such momentous results, and referring to his own work on freshwater Cyclops which retain their individual characters within a wide pH range.

WE have now a communication from Prof. Labbé in support of his own observations, upholding the identifications in spite of criticisms, his contention being that Mr. Gurney could not possibly prove that forms were identical which he did not see. He suggests sending to Mr. Gurney a lot of the copepods for analysis; an offer which we hope will be accepted. Secondly, in answer to Mr. Lowndes he agrees that freshwater copepods can often bear a much greater range of pH than those in salt water, but holds that variation in pH will not necessarily bring about morphological variation. Thus the quoted Artemia showed no change, whatever the variation in pH. On the other hand, with small change in surroundings alteration may take place. As he says, "Allelogenesis is likely to succeed only under proper conditions of equilibrium between inner and outer pH." To find such conditions "is the fundamental problem of allelogenesis, which I have not yet solved." Prof. Labbé quotes his previous work on the cycles of Dunaliella as suggesting some solution of the problem of internal adjustment, and finally states that he will carry on his researches 'quite undisturbed.' It is to be hoped that he will bring forward more exact descriptive and experimental evidence in support of his interesting and revolutionary statements.

We much regret to announce the death on Mar. 4, at the age of seventy-five years, of Sir Aubrey Strahan, K.B.E., F.R.S., lately Director of the Geological Survey of Great Britain, and of the Museum of Practical Geology, London.

The Council of the British Association will nominate Sir Thomas Holland, rector of the Imperial College of Science and Technology, as president of the Association for the meeting to be held in South Africa in July and August 1929. Mr. O. J. R. Howarth, Secretary of the Association, expects to proceed to South Africa in May next to confer with authorities there on arrangements for the meeting.

Mr. W. L. Hichens, chairman of Messrs. Cammell, Laird and Co., and well known for his work in scientific administration and industry, has been elected a member of the Athenæum Club under Rule II., which provides for election by the Committee of "persons of distinguished eminence in science, literature, or the arts, or for public services."

The following officers were elected at the annual general meeting of the Geological Society of London, held on Feb. 17: *President*, Prof. J. W. Gregory; *Vice-Presidents*, Dr. F. A. Bather, Prof. E. J. Garwood, Dr. E. Greenly, and Mr. H. W. Monckton; *Secretaries*, Mr. W. Campbell Smith and Dr. J. A. Douglas; *Foreign Secretary*, Sir Arthur Smith Woodward; *Treasurer*, Mr. R. S. Herries.

Dr. W. Rosenhain, Superintendent of the Metallurgy Department of the National Physical Laboratory, Teddington, since 1906, has been elected president of the Institute of Metals for 1928-29. Dr. Rosenhain is a graduate of the University of Melbourne, Australia, whence he came to England in 1892 with a research scholarship of the Commissioners of the 1851 Exhibition. He has carried out a large amount of metallurgical research both on non-ferrous metals and on iron and steel, and is also well known in connexion with glass technology.

Dr. Herbert E. Ives, who recently received the John Scott medal and premium for his contributions to electrical telephotography and television, has given the amount of the premium (1000 dollars) to the Optical Society of America, to found and endow a medal. This medal, to be awarded every two years for distinguished work in optics, is to be named "The Frederic Ives Medal," in honour of the donor's father.

A conference on "Malting Barley" will be held at the Rothamsted Experimental Station at 11.30, on Thursday, Mar. 15. The subjects of the addresses to be delivered are "What the Barley Buyers Want"; "The Influence of Season on the Yield and Quality of Barley"; "Cultivation and Treatment of Barley grown for Malting in the Vale of Taunton"; "Cultivation and Treatment of Barley grown for Malting on the Lincolnshire Heath"; "Malting Barley: Old and New Varieties"; and "Five Years' Experiments on Malting Barley."

At a meeting of the Royal Society of Edinburgh held on Mar. 5, the following were elected fellows of the Society: Dr. E. A. Baker (Edinburgh), Prof. G. B. Barbour (Peking), Mr. H. W. Brown (Edinburgh), Rev. Dr. W. S. Bruce (Banff), Prof. A. J. Clark (Edinburgh), Dr. A. Couttie (Edinburgh), Dr. W. Murdoch Cumming (Glasgow), Mr. W. R. Dawson (London), Mr. E. W. Fenton (Edinburgh), Dr. James Forrest (Dundee), Prof. J. Fraser (Edinburgh), Dr. K. Fraser (Carlisle), Mr. W. G. Harding (Oxford), Mr. A. D. Hobson (Edinburgh), Mr. W. V. D. Hodge (Bristol), Dr. A. Hunter (New York), Mr. P. J. Johnston-Saint (London), Prof. R. W. Johnstone (Edinburgh), Dr. T. J. Jones (Liverpool), Mr. T. L. MacDonald (Glasgow), Prof. T. J. Mackie (Edinburgh), Prof. G. Matthai (Lahore), Dr. J. E. Nichols (Edinburgh), Dr. C. H. O'Donoghue (Edinburgh), Dr. G. H. Percival (Edinburgh), Mr. R. S. Pilcher (Edinburgh), Mr. C. E. Price (Edinburgh), Mr. O. F. T. Roberts (Aberdeen), Mr. R. Senior-White (Kasauli, India), Mr. A. D. B. Smith (Edinburgh), Mr. A. M. Watters (Hawick), Mr. J. M. Whittaker (Edinburgh), Dr. J. Williamson (St. Andrews).

The fifth International Botanical Congress will be held at Cambridge on Aug. 16–23, 1930, with excursions during the following week. As at present arranged, the Congress will be organised in the following sections: Palæobotany, morphology (including anatomy), taxonomy and nomenclature, plant geography and ecology, genetics and cytology, plant physiology, mycology and plant pathology. For each of these sections a British sub-committee has been appointed, by which the programme will be arranged. The chairmen of these sub-committees and their addresses are as follows: Palæobotany, Prof. A. C. Seward, Botany School, Cambridge; morphology (including anatomy), Prof. F. E. Fritsch, Danesmount, Tower Hill, Dorking, Surrey; taxonomy and nomenclature, Dr. A. W. Hill, Royal Botanic Gardens, Kew, Surrey; plant geography and ecology, Prof. A. G. Tansley, Department of Botany, The University, Oxford; genetics and cytology, Sir John Farmer, Imperial College of Science and Technology, London, S.W.7; plant physiology, Dr. F. F. Blackman, Botany School, Cambridge; mycology and plant pathology, Dr. E. J. Butler, Imperial Bureau of Mycology, 17 Kew Green, Kew, Surrey. Communications made to the Congress by means of papers or by participation in the general discussions will be permissible in English, French, or German. An executive committee of British botanists has been appointed, with Prof. Seward as chairman, to make the necessary arrangements; Dr. A. B. Rendle is acting as honorary treasurer, and Mr. F. T. Brooks, 31 Tenison Avenue, Cambridge, and Dr. T. F. Chipp, Royal Botanic Gardens, Kew, are honorary secretaries of the Congress.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A teacher of woodwork and geometry at the Walthamstow Technical College—The Clerk to the Governors, 1 Selbourne Road, E.17 (Mar. 12). An assistant master for mathematics and science at the Acton and Chiswick Polytechnic Junior Technical School—The Principal, The Polytechnic, Bath Road, Chiswick, W.4 (Mar. 16). A principal and head of the metallurgical department of the County Technical College, Wednesbury—The Director of Education, County Education Offices, Stafford (Mar. 23). A full-time teacher of engineering subjects at the Shrewsbury Technical College—The Secretary to the Committee of Management, Guildhall, Shrewsbury (Mar. 27). A biochemist and a protozoologist at the Medical Research Institute in Nigeria—The Private Secretary (Appointments), Colonial Office, 2 Richmond Terrace, Whitehall, S.W.1 (Mar. 31). Inspectors of agriculture under the Department of Agriculture and Forests of the Sudan Government—The Controller, Sudan Government, London Official, Wellington House, Buckingham Gate, S.W.1 (April 7). A professor of organic chemistry in the Central College, Bangalore, University of Mysore—The Registrar, University of Mysore, Mysore, India (April 25). A junior assistant in the Research Department, Woolwich (under the directorate of Explosive Research)—The Chief Superintendent, Research Department, Woolwich, S.E.18.

ERRATUM.—In NATURE of Mar. 3, p. 315, col. 2, lines 20 and 24, it was stated that Prof. A. V. Hill had calculated that the Woolworth Building in New York could be climbed in eight seconds, and that it had been done in nine seconds. These times should be eight minutes and nine minutes respectively.

Our Astronomical Column.

COMETS.—After the discovery of Reinmuth's comet, an examination was made of earlier plates taken at Konigstuhl, with the result that the following position of the comet was derived: Jan. 29·10757 U.T.; R.A. 9h 23m 35s·6; N. Decl. 17° 41′ 19″; from this position, combined with those of Feb. 22 and 25, Dr. A. C. D. Crommelin has derived the following elliptical orbit (the position for Feb. 22, on revision of measures, was given as 9h 15m 7s·5, N. Decl. 21° 44′ 55″):

$$\begin{array}{ll} T & 1928 \text{ Feb. } 1{\cdot}6502 \text{ U.T.} \\ \omega & \left.\begin{array}{l} 9^\circ\ 26'\ 37'' \\ 124\ \ 53\ \ 11 \\ 8\ \ \ 0\ \ 16 \end{array}\right\}1928{\cdot}0 \\ \Omega & \\ i & \\ \phi & 30\ \ \ 2\ \ 13 \\ \log a & 0{\cdot}5701080 \\ \log q & 0\ 2685923 \\ \text{Period} & 7{\cdot}164106 \text{ years.} \end{array}$$

The following ephemeris is for 0 h. U.T.:

	R.A.	N. Decl	log r	log Δ.
Mar. 8	9h 14m 31s	23° 8′	0·2748	9·9889
16	9 16 44	23 31	0·2778	0·0132
24	9 20 54	23 35	0·2814	0·0402

The orbit does not closely resemble that of any comet in the catalogues, but there is a distant resemblance to that of Denning's comet, 1894 I. It is of interest that the aphelion point of the above orbit lies close to the perihelion point of comet Schwassmann-Wachmann, and the two comets were close together in the middle of 1924, if the orbit of Reinmuth is near the truth; it represents within 2¼′ an observation made at Milan on Feb. 28.

Mr. James Young obtained a photograph of Encke's comet, Feb. 6 7708 U.T., from which he derives the following position: R.A. 22h 49m 54·5s, N. Decl. 0° 18′ 55″. This gives Feb. 19·829 for the date of perihelion, which is 3 hours later than Matkiewicz's predicted date, Feb. 19·6984, rather an unexpectedly large discordance. The acceleration of this comet, which formerly attracted so much attention, seems to have completely died away. This renders it difficult to explain the acceleration by resisting medium, as such a medium could scarcely have been present in the last century and absent now.

Mon. Not. Roy. Astro. Soc. for January contains reproductions of the drawings of Skjellerup's comet by Mr. Chidambara Aiyar on Dec. 15, when it was about 2° from the sun.

THE DRAYSON PARADOX.—This paradox had its sole basis in a carelessly written paragraph in Sir J. Herschel's "Outlines of Astronomy." It asserts that the pole of the equator moves around a centre that is 6° distant from the pole of the ecliptic, so that the obliquity varies between 23½° and 35½°; the ice-ages are asserted to have occurred at the epochs of maximum obliquity. Drayson also erroneously claimed that the proper motions of stars were merely an effect of this movement of the earth's axis.

The observational evidence against the Drayson theory, and its lack of a dynamical basis, have been frequently brought before the public during the last half-century, but it still claims adherents. Mr. A. H. Barley, its principal advocate, has recently brought out a pamphlet, "The Ice Age" (W. E. Baxter, Ltd., Lewes, Sussex), in which the old assertions of Drayson are repeated, and the further claim made that the very small errors in the predictions concerning the recent solar eclipse (spoken of as 'serious errors' in the pamphlet) were due to the non-acceptance of Drayson's views. The argument here is a repetition of that used by Mr. E. J. Stone in several papers between 1883 and 1892; he ascribed the errors of Hansen's lunar tables to a change in the ratio of mean to sidereal time, brought about by the substitution of new solar tables in the *Nautical Almanac*. He was correct in asserting that some such change took place, but he multiplied its effect by 365; Sir G. Airy showed in a letter to the *Observatory* in May 1883 that sidereal time, from the manner in which it was derived, could not be in error by the amount that Stone asserted.

Prof. de Sitter discussed the errors of the lunar tables in NATURE of Jan. 21, p. 99, and gave the evidence in favour of the conclusion that they are due to small variations in the earth's rate of rotation, not to changes in the direction of its axis.

Research Items.

Hawaiian Jaws and Teeth.—Mr. H. G. Chappel has examined the collection of Hawaiian mandibles, both those attached to crania and those without crania, and mostly dating from before the coming of the white man, in the Bernice P. Bishop Museum, Honolulu, with a view to the study of the teeth and dental disease. The results are published in *Memoirs of the Bernice P. Bishop Museum*, vol. 9, pt. 3. The teeth show comparatively little irregularity, only 9·9 per cent. Only 17·2 per cent. have the incisor knocked out as a sign of grief for a relative. This custom was more prevalent among the men than the women, and on Hawaii than on the other islands. There is little caries owing to developmental faults. From forty to sixty years of age it increases considerably, and is more prevalent in mandibular than in the maxillary teeth. Alveolar abscesses grow more prevalent as age advances, as does pyorrhea; between forty and sixty years of age only 6·57 per cent. are free from it. As regards the jaws, there are more orthognathous females than males and little prognathism in either sex. The majority of males and females show a greater height and width of the ramus of the mandible on the left side and a greater height of the body of the mandible on the right side. The males of the island of Hawaii show a greater bigonal width than those of the other islands.

Cancer Statistics.—The Ministry of Health has issued two further reports on cancer. One of these (*Reports on Pub. Health and Med. Subjects*, No. 46) deals with cancer of the rectum, and is based on an examination, by the Departmental Committee, of the records of rather less than 6000 cases of this disease. It is found that, on an average, the patients did not come to operation until twelve months after the occurrence of the first symptoms, and that rather less than half the patients when seen by the surgeons were considered to be operable. Of those operated on, about one-sixth died as the result of such operation, sepsis being the cause of half these deaths, but two out of every five were alive three years afterwards. The other report (*ib.*, No. 47) deals with the treatment of cancer of the uterus at the Samaritan Free Hospital, and has been prepared by Dr. Janet Lane-Claypon and Mr. W. M'K. H. M'Cullagh. Again the same fact emerges that something like half the patients are inoperable when they present themselves, and that the first symptoms were noticed six months previously. The operative mortality in cancer of the cervix was only about 6–7 per cent., and the number surviving five years after hysterectomy was about 34 per cent. for the vaginal, and 44 per cent. for the abdominal operation. For cancer of the body of the uterus, the number surviving five years after operation was 61·5 per cent. It has long been recognised that childbirth is a predisposing cause of cancer of the cervix, and the data here collected suggest that there is also a definite association of the disease with early miscarriage before the fœtus is viable. Many other details have also been analysed in the two reports, such as the earliest symptoms of the disease noticed by the patients, the mortality of various operative procedures and the chief causes of death therefrom, and the duration of life without operation.

Harmful Noise.—The Engineering Section of the National Safety Council, at its sixteenth annual congress, held at Chicago on Sept. 26-30 last, reports the results of a research committee set up to deal with the elimination of harmful noise. The report begins by attempting to define noise, but admits that the line of demarcation between musical sound and noise cannot be sharply drawn. The interest in noise elimination is widespread, and many articles have appeared throughout America during the year. Dr. E. E. Free made a noise survey of the city of New York, and Mr. R. F. Novis of Chicago. Such surveys, however, cannot be utilised as a basis for determining which noise should be eliminated and which may be tolerated. People who are ill can tolerate only a minimum of noise, but no one knows what noises are harmful, or how much noise is harmful to people who are not ill. Several attempts have been made to measure the effect of noise upon the human organism, but so far the data for formulating a definition of harmful noise are not available. The report suggests that the services of physiologists, neurologists, otologists, psychologists, and physicists should be enlisted in order to investigate the problem. Prof. John J. B. Morgan, of Northwestern University, has made a preliminary study of the effects of noise by comparing the electrocardiograph records of subjects in a quiet and in a noisy environment. The noises were produced by Western Electric audiometers, the sound being amplified and given to the subjects through a loud-speaking telephone. Prof. Morgan's tentative conclusions are (1) that the heart action is modified by the noise, but that the effect is more apparent in the irregularity of the action than in the average rate; (2) that subjects vary in the way they respond and that different sounds have different effects; (3) that the suggestion of a 'horrible din' to a hypnotised subject quickens the pulse, thus indicating that the emotional attitude towards the sound may be of greater significance than the quality of the sound itself. The report concludes that the method indicates a way of approach to the very difficult problem of harmful noise.

Zoological Studies of Central Asia.—The Commission for the Study of Natural Resources of the Russian Academy of Sciences has just published a list of literature on animals of Turkestan, compiled by M. M. Ivanova-Berg, under the editorship of Prof. Leo Berg. The list comprises a volume of large size, 235 pp. in all, and covers all literature on animals of Central Asia, both wild and domestic. Central Asia is given wide limits, and includes the Kirghiz steppes, Turkestan, Dzhungaria, Kashmir, N.W. India, Afghanistan, and northern Persia, but the literature on the fauna of the Caspian Sea is not included, except that dealing with fisheries on the eastern coast. Russian literature is dealt with very exhaustively, but it is not claimed that foreign papers are fully represented. The total number of entries is 4894. Titles are classified; first are quoted systematic, zoogeographical, and similar papers on each group; then a section on pests of agriculture follows; another special section on locusts (more than 300 entries); then fisheries; animal breeding generally and by branches; bee-keeping; silkworm industry. Two supplements bring the bibliography practically up to the end of 1927. Two indexes, one of geographical names mentioned in titles, another of species of animals, conclude this volume, which will be found very useful by anyone working on scientific or economic problems of Central Asia.

Polyzoa from the Adriatic and Mediterranean.—Dr. Antonia Neviani ("La *Schizotheca serratimargo* Hks. sp. nell' Adriatico e suoi ospiti." *Memorie della Pont. Accademia delle Scienze—I nuovi Lincei*, Ser. 2, vol. 10) redescribes this interesting species, first discovered by Hincks in 1886 from the Adriatic, and, although only fragments were then obtained, attributed by him to the genus Schizoporella. Dr. Neviani, having succeeded in finding several fine specimens in the Mediterranean, gives a detailed account of these, together with other encrusting polyzoa growing on them. *Schizotheca serratimargo*, as it is now called, is a calcareous polyzoon living in the coralline zone attached to various stones, shells, madrepores, and nullipores from the Mediterranean and the Adriatic Seas, the Suez Canal, and the coast of Morocco, also occurring fossil in the Pliocene and post-Pliocene of Italy. A full list of records is given, showing that from 1909, when it was recorded by Waters from the Red Sea, it was not again mentioned until 1925, when Canu and Bassler included it in their list of Bryozoa from Morocco and Mauritius. It is unfortunately exceedingly delicate to handle and breaks up at the slightest touch. The 'guests' or animals growing upon it include Spirorbis and serpulids and five species of calcareous polyzoa, all belonging to different genera.

PARASITES OF THE EUROPEAN CORN BORER.—*Circular No. 14* (Oct. 1927) of the United States Dept. of Agriculture embodies a résumé of the present status of imported parasites of the European corn borer. The authors, Messrs. D. W. Jones and D. J. Caffrey, mention that since native parasites do not effectively attack this insect, it has been deemed necessary to import certain species which parasitise it in its original habitat in France, Belgium, Italy, and Hungary. Twelve different species of parasites have been introduced into the United States between 1920 and 1927, numbering more than 355,000 individuals. All these were sent to the Corn Borer Laboratory at Arlington, Mass., and from there distributed, after they had mated, among infested areas. A certain number of parasites were kept back in order to build up an increased stock before liberation, and in this way 1,535,000 additional parasites were obtained. Systematic collections and observations in the vicinities where these liberations took place, have resulted in the recovery of six of the species concerned in circumstances indicating that they have become established in the United States, and that they are actually preying upon the corn borer. Although strenuous efforts are being made to import, breed, and establish these various parasites in corn borer infested areas, it is too early at present to decide whether they will prove effective aids in controlling the pest. Judging from the experience with similar parasites imported to aid in controlling other foreign pests, several years will elapse before any important effect can be expected. In the meantime, every effort to control the corn borer by other methods needs to be assiduously maintained.

GENETICS OF CHERRIES.—In a study of the genus Prunus, including the plums and cherries, Mr. C. D. Darlington (*Jour. of Genetics*, vol. 19, No. 2) finds that 8 is the basal number of chromosomes and that many of the species and varieties are polyploid. The chromosome number runs so high as 48, and some varieties have chromosome numbers which are aneuploid (not an even multiple). Self-sterility is prevalent and hybridisation has occurred between different forms. This has created a swarm of hybrid forms which render impossible any clear demarcation between species with the same number of chromosomes. Homologous series of variations also occur in Prunus, which are attributed to crossing and segregation among related types. The sweet cherries (*P. avium*) have some trivalent chromosomes, the total number of chromosomes being $2n = 17-19$. The sour and Duke cherries (*P. cerasus*) are tetraploid ($2n = 32$), and the bivalent chromosomes are often grouped in pairs at meiosis. The sweet cherries are of ancient cultivation, but the Duke varieties, developed largely in the seventeenth century, are regarded as aberrant $4n$ segregates from diploid gametes of sweet cherries, perpetuated by grafting. Tetraploidy also has the effect of removing the bar to self-fertility. It is found that cherries which are diploid, or nearly so, can produce tetraploid seedlings, and vice versa.

MENDELIAN GENES AND DEVELOPMENT.—The Amphipod *Gammarus chevreuxi* has provided useful material for genetic study. Messrs. E. B. Ford and J. S. Huxley (*Brit. Jour. Exptl. Biol.*, vol. 5, No. 2) have made an analysis from a developmental point of view of the factors controlling eye-colour. The normal black-eyed type gives rise to various mutational eye-colours, such as red, which may differ not only in the final adult colour, but also in the rate at which pigment is deposited. Segregation for slow or rapid development of the pigmentation may occur in a simple mono-hybrid ratio, but in certain families an apparent failure to segregate was found to be due to accessory rate-factors. Many of the facet-colour genes therefore influence the time relationships governing the deposition of melanin, all coloured eyes passing from colourless through scarlet; later they may darken to black by the addition of melanin. Graphs for developmental rates of different factors are given, and conditions which may bear a similar interpretation in various other animals are discussed. It is suggested that a multiple allelomorph series may represent the developmental curves of a single substance, differing in rate of formation of the substance, time of beginning deposition, and equilibrium position finally reached.

NEW CARBONIFEROUS PELECYPODA.—An important little paper on certain Carboniferous Pelecypoda, or, as he prefers to call them, lamellibranchs, has just been published by Mr. J. Wilfrid Jackson of the Manchester Museum (*Mem. and Proc. Manchester Lit. and Phil. Soc.*, vol. 71, No. 10: reprinted as *Notes from the Manchester Museum*, No. 31). The genera dealt with are Pterinopecten, Posidonomya, and Posidoniella. The author shows that more than one form has been included in the first-named genus as *P. papyraceus* (Sow.) and distinguishes five species. The differences between them depend on surface ornamentation, and occur on specimens from different horizons, but are not so marked as those exhibited by contemporary Goniatites, nor are the various species of equivalent value to the Goniatites for zonal purposes, mainly owing to the scarcity of well preserved specimens. Two new species of Posidoniella are also described. The paper is illustrated by three very good plates.

CRYSTALLINE CARNOTITE.—The usual carnotite deposits of the plateau region of Utah and Colorado are impregnations in sandstone formed when the rocks were first exposed to the percolation of meteoric waters. Geologically this date has been placed in the Eocene, and the lead-ratios indicate a numerical age of at least 42 million years, in good agreement. A discovery of crystalline carnotite has now been made in a situation near the upper end of the Grand Canyon, where the date of formation would be considerably later in the Tertiary. This unique material is thoroughly described by F. L. Hess and W. F. Foshag in the *Proc. U.S. Nat. Mus.*, vol. 72, art. 12, 1927. Lead is present, as shown by spectroscopic tests, but in quantities too small to be determined chemically in the limited samples available. However, the age was estimated from a measurement of the proportional radioactivity. The radium–uranium ratio was found to be only 68 per cent. of the normal ratio, corresponding to an age of 6·8 million years, which agrees well with the geological indications With further investigations of this kind it will become possible to date the various stages in the history of the Grand Canyon from the Eocene to the present day.

Survey Work in the United States —Among the many accomplishments of the United States coast and geodetic survey for the year ending June 1927, the *Annual Report* directs particular attention to three of importance. The first is the completion of the field work necessary to make a readjustment of the first order triangulation west of the ninety-eighth meridian. The second is the investigation of the first order level net of the United States. The adjustments started from Galveston and were carried to the Pacific and Atlantic coasts. This levelling shows that mean sea-level on the Atlantic coast is more than a foot above mean sea-level on the Pacific coast. The third notable achievement was of a different nature, namely, the construction of a light movable steel tower for use in triangulation in flat regions. The use of this improved tower is expected to reduce the cost of first order triangulation in level lands as much as 25 per cent. A further advance in survey methods is the adoption by all the vessels of the survey of echo-sounding apparatus. After extensive tests and modifications, a satisfactory apparatus has been developed. The *Report* contains key maps of the state of various surveys.

Are Auroræ Accompanied by Noises ?—Reports of swishing sounds accompanying auroral displays are common, but are still regarded with doubt, because of the difficulty of reconciling the production of such sounds at low levels with the extreme rarity and altitude (about 100 km.) at which auroræ appear. There have, however, occasionally been reports of auroræ being seen at much lower levels , some years ago, in a letter to Nature, Dr. G C Simpson discussed various cases of the kind; including some instances in which he was able personally to investigate the report on the spot ; his conclusion was that in these cases the effect was an optical illusion Another report of a low level aurora, by Mr. J H. Johnson, appeared in the December (1927) issue of the *Publications of the Astronomical Society of the Pacific.* " A singular aurora—an array of dancing streamers having prismatic colours," accompanied by swishing sounds, was seen at Eagle, Alaska, 64° 47′ N., 141° 10′ W. in front of a bluff half a mile away, which rises to a height of 1200 feet above the town There seems to be no reason to doubt that a remarkable luminous phenomenon occurred not far from the observer, and at less than 1000 feet above ground level ; but it must have been of a very different character from that usually called an aurora. Even the top of the streamers did not appear above the summit of the bluff, and no mention is made of the presence, at the same time, of high-level aurora properly so-called.

New Results with Soft X-rays.—In a recent paper in the *Journal de Physique* (vol. 8, p. 484) J. Thibaud and A. Soltan have directed attention to differences between their measurements of wave-lengths betwen 40 A. and 80 A., made with a ruled grating, and those made by Dauvillier with a crystal. The latter, if calculated directly from the Bragg formula, are always too high, apparently because the index of refraction of the material used differs from unity by as much as 0·01 in this region. Their own results include new values for the *K* lines of nitrogen and boron, and for the *N* and *O* rays of several heavy elements, and have enabled them to find the energies of the *L* level for the lighter elements. The *N* rays examined consist of regular doublets. In a later note in *Comptes rendus*, it is reported that continuous spectra are also present in association with the characteristic soft X-rays, if heavier currents are passed through the generating tubes (Nature, Mar. 3, p. 321).

A New Separating Funnel.—In the *Chemiker Zeitung* for Jan. 25 is a description of a new form of separating funnel, consisting of a combination of two stoppered pear-shaped bulbs, between which is inserted a 3-way stop-cock. Each of the bulbs carries an elongated hollow stopper of special design. The new funnel, which offers considerable advantages over the older type, is in use in the technological laboratory of the Chemical Institute at Buda-Pesth.

Measurement of the Concentration of Dilute Solutions —The accurate determination of concentrations of dilute solutions of organic compounds is a matter of considerable difficulty when the usual methods of analysis are employed. It is possible to utilise the interference refractometer for this purpose to obtain rapid and accurate measurements, and some of the difficulties encountered in the calibration of the Zeiss interferometer are discussed by R Macy in the *Journal of the American Chemical Society* for December 1927. A greater degree of accuracy is attainable with solutions of aromatic than with solutions of aliphatic compounds, and the reading for two substances in the same solution is very nearly the sum of the separate readings for each.

Adsorption of Oxygen on Charcoal.—Using four different types of charcoal, A. F. H Ward and E. K. Rideal have investigated the adsorption and heat of adsorption of oxygen, the rate of autoxidation, the area of methylene blue adsorption, the ash content, the true and apparent bulk densities, and the particle size, and an account of their work is contained in the *Journal of the Chemical Society* for December 1927. In the case of a charcoal with a large ash content, the initial heat of adsorption for oxygen was very high and the carbon surface appeared to be unstable. For the other charcoals, the areas of the active portions were found to be proportional to the rates of autoxidation and were of the same order as when determined from the poisoning of autoxidation by amyl alcohol. The results obtained do not support the supposition of Keyes and Marshall that the high initial heat of adsorption corresponds to the establishment of a unimolecular layer and that the lower subsequent heats are due to the building up of thicker oxygen films.

The Reactions between Oxygen and Coal.—An investigation of the spontaneous combustion of coal is being carried out by the Safety in Mines Research Board, and some of the results obtained are described by Messrs W. Francis and R. V. Wheeler in the *Journal of the Chemical Society* for December 1927. The amounts of oxygen fixed by the vitrain portion of newly won coal and by vitrain from the same seam after prolonged atmospheric oxidation at 150° C. were measured at various temperatures, and the quantities of the products of the reaction determined. The oxidation of coal appears to take place by the formation of unstable oxygenated groupings, which are carboxylic in character and ultimately cause the ulmin portion to become soluble in alkalis. The reaction seems to depend upon the presence of an adsorbed layer of oxygen, which is continually renewed so long as oxygen enters into combination. The oxygenated groupings are decomposed into water and oxides of carbon and the coal ' revivified ' by heating in a vacuum.

Medical Research.

THE thirteenth annual report of the Medical Research Council[1] gives, as usual, a summary of research work covering a very wide field; some of the more important aspects of this work only will be referred to here. At the end of the year under review Sir Frederick W. Andrewes and Sir Cuthbert S. Wallace retired from the Council, their places being taken by Sir Hugh K. Anderson and Prof. T. R. Elliott. The work of the Council has suffered by the deaths of Dr. John Brownlee, Director of the Statistical Department, of Dr. T. S. P. Strangeways, well known for his work on the artificial culture of cells and tissues, and of Prof. E. H. Starling, who was chairman of the committee on the physiology of muscular work, under the Industrial Fatigue Research Board. As in previous years, reference is made to the effective augmentation of the resources of the Council by the facilities provided by the universities and other centres of research throughout Great Britain to research workers who are advancing knowledge under grants provided by the Council. Payments towards the cost of particular investigations have also been made by the Miners' Welfare Fund, the Dental Board of the United Kingdom, the Empire Marketing Board, the Distemper Research Council of the *Field* newspaper, the British Empire Cancer Campaign, the trustees of the late Sir William Dunn, and by an anonymous donor for a microscope designed by Mr. J. E. Barnard.

During the year the Council has worked in close co-operation with many Government departments, with the Development Commission, the Department of Scientific and Industrial Research, and the newly constituted Colonial Medical Research Committee. The Report points out that it should now be recognised that medical science is one and indivisible, and that laboratory investigations into tropical diseases may be more usefully carried out in a temperate climate, whilst observations on measles or tuberculosis may be more fruitful of results when made in the tropics. It is hoped that eventually an 'Imperial Research Service' may be built up by which problems of nutrition or disease may be readily investigated wherever it is convenient and the results applied wherever they are required.

BIOLOGICAL STANDARDS.

During the year the Therapeutic Substances Act 1925 came into operation, and standard preparations are now required for the assay of diphtheria and tetanus antitoxins, antidysentery serum (Shiga), old tuberculin, insulin, pituitary (posterior lobe) extract, arsenobenzene, novarsenobenzene, and sulpharsenobenzene. Standard solutions of the antitoxins and of the serum are distributed at regular intervals to all licensees for the manufacture of these substances under the Act; standard preparations of insulin and of pituitary posterior lobe have similarly been distributed. The standards of the arsenical derivatives are held at the National Institute for Medical Research, where also the routine testing of all batches of these drugs is carried out. The standards agree with those accepted or recommended by the health organisation of the League of Nations in all cases in which an international standard has been adopted. At the present time an international investigation is proceeding into the potency of scarlatina streptococcal toxin and antitoxin, with a view to the eventual creation of a standard and the definition of acceptable units. The demand for standard agglutinable cultures and sera, prepared at the Standards Laboratory at Oxford under the direction of Prof. G. Dreyer, has continued to increase; the Council has decided that the whole cost of the laboratory cannot be met from its funds, and during the year the system of making charges for such standard preparations was adopted, without greatly affecting the demand for them.

BASIC CONSTITUENTS OF THE TISSUES.

In recent years it has become clear that a number of different bases can be extracted from normal tissues. Some have been known for a long time, but only recently has any evidence been obtained as to their possible functions; others have only recently been isolated, and their physiological properties have still to be investigated. In last year's report the successful synthesis of spermine

$$(NH_2 \cdot (CH_2)_3 \cdot NH \cdot (CH_2)_4 \cdot NH \cdot (CH_2)_3 \cdot NH_2)$$

by Dudley and Rosenheim was referred to; from the current report it is seen that the same authors, working with W. W. Starling, have isolated, identified, and synthesised a new base, spermidine

$$(NH_2 \cdot (CH_2)_3 \cdot NH \cdot (CH_2)_4 \cdot NH_2),$$

which is present in the tissues together with spermine. Although the latter was first discovered in sperm, it appears to be a constituent of most tissues and not to bear any particular relationship to the reproductive processes; it is, in fact, absent from bull's semen, eggs, and milk.

The most abundant and the longest known of the nitrogenous extractives of muscle is creatine, but until the past year we held no clue as to its function. It has now been shown by P. Eggleton to exist during life in the form of an unstable compound with phosphoric acid in equimolecular proportions which is broken down in contraction and resynthesised during subsequent rest in the presence of oxygen; it can be isolated from rabbit muscle in the form of a barium salt. Hence the creatine complex plays a part in the chemical processes accompanying contraction, as well as the glycogen and lactic acid; it is connected apparently with the velocity of contraction. The next most abundant base in muscle is the peptide carnosine; Dudley and Thorpe have prepared a large quantity of it, and are at present investigating its properties and reactions. This work was undertaken following an examination of muscle for the base histamine, after Best, Dale, Dudley and Thorpe had extracted it from both liver and lung; it was found that muscle also contained it. Histamine, together with choline, appears to be responsible for the depressor effect of all tissue extracts (except those from the suprarenal and pituitary glands, which are pressor), upon the blood pressure; its effect in this respect is due to its dilating the capillaries; at the same time it stimulates most smooth muscular tissues and thus produces also constriction of the arteries, but the former effect is the more important, since it is produced by much smaller doses.

Particular importance has been lent to this identification of histamine in many tissues by the work of Sir Thomas Lewis and his collaborators on the reactions of the blood-vessels of the skin in man to injury. These investigators have brought forward much evidence to show that almost all forms of injury or irritation act in a similar way by causing the liberation of a chemical substance allied to histamine (or quite probably histamine itself), to which the reddening and swelling of the skin are due. After the application of various stimuli or of histamine, these cutaneous blood-vessels contract imperfectly or not at all to adrenalin or pituitary extract, and also become refractory to histamine itself. It is possible that the collections of small dilated blood-vessels which appear on the face as age advances or following much exposure to the weather, are also caused by over-stimulation of the skin, since they are refractory to the stimulus of these different hormones. If these conclusions can be extended from the skin blood-vessels to those of the deeper tissues, they should influence considerably our conception of the reactions of different organs to injury or to nervous stimulation.

---

Therapeutics.

The year 1927 saw the centenary of the publication by Richard Bright of his observations on kidney disease. A. A. Osman, applying modern methods of biochemistry to the study of Bright's disease, has found that administration of alkalis is of great benefit in treatment and in prophylaxis, and has been able, further, by means of simple tests, to demonstrate the type of case likely to suffer from nephritis as a complication of other diseases, especially scarlet fever. Thus the incidence of nephritis and albuminuria in 316 untreated cases of scarlet fever was 5·5 per cent., but in 620 cases treated by alkalis it was only 0·6 per cent. Again, alkalis can effectively prevent the onset of anuria under conditions in which this symptom may occur, and also the appearance of nephritis in metallic poisoning, or in poisoning with general anæsthetics or after exposure to infection. The after-effects of nephritis have also been studied in a group of more than 10,000 patients who suffered from this disease during the War. In many of them the original kidney lesion has cleared up, leaving behind, however, as sequelæ, cardio-vascular impairments with high blood pressure. This study may throw light on the origin of certain cases of high blood pressure for which at present no definite cause can be found.

During the year a report by J. G. Forbes has been published dealing with the prevention of diphtheria; susceptible individuals can be detected by the Schick test and protected against the disease by toxoid-antitoxin immunisation. An important step forward in the control of this disease appears to have been taken.

King and his colleagues have continued their syntheses of substances likely to have a chemo-therapeutic action; about 50 colourless compounds, closely related to complex dyes, have been examined for trypanocidal activity by Miss Durban and Miss Marchal, and a relationship has been found between the appearance and intensification of curative action on one hand and of affinity for cotton fibres on the other. King and Balaban have also examined some gold and mercury derivatives of the thioglyoxalines. One of the gold compounds, containing 58 per cent. of the metal in soluble combination, appears to have some curative action in experimental tuberculosis (Douglas). In human patients suffering from tuberculosis, another gold compound, sanocrysin, exerts, in selected cases, a favourable influence; in animals it appears to be effective only in those having enough resistance to enable them to exploit the temporary advantage, whatever it may be, given by the drug.

Cohen and Browning have examined the trypanocidal properties of aminostyrylquinoline and amino-anilquinoline compounds. In connexion with this work it has been shown that substances which are retained in the body and exert their therapeutic action slowly, are effective by killing only a few of the parasites, products from which stimulate the tissues to produce antibodies which destroy the remainder. Further, if a subtherapeutic dose of a chemotherapeutic substance such as crystal violet be given a short time before a curative dose of an arsenical compound, etc., the injection of the latter may be ineffective; this observation has an obvious and important bearing on practical therapeutics.

Colebrook and Hare have found that by proper spacing of the doses of organic arsenical compounds it is possible to produce and maintain a bactericidal potency of the blood against streptococcal infections. These authors have also made the interesting observation that the white blood corpuscles of patients suffering from severe streptococcal infections are much more sensitive to the toxic action of arsenical compounds than those from healthy individuals.

Pathology.

In investigations into tuberculosis, A. S. Griffith has shown that the bovine bacillus is the chief cause of the disease in domestic mammals; it was, in fact, the only type found in the horse, cat, and goat. In sheep, and especially in swine, the avian type of the bacillus is also found. The human type occurs in the dog, and also in wild animals kept in captivity. In man a high proportion of tuberculosis is directly due to the bovine bacillus, conveyed chiefly through the medium of infected milk, emphasising the importance of the elimination of this disease from dairy cattle.

Hill and Brad have continued their investigations into the effects of diet upon reproductive power and liability to cancer in mice. The natural span of life appears to be about three years. Five diets have been used: grain and green food; cooked meat, vegetables, pudding, tinned fruit, and salt; white bread, margarine cakes, biscuits and a little milk; a low protein diet and the same diet with one-third browned by frying. Breeding is good except on the third (or white bread) diet. Cancer occurs fairly frequently in the older mice; in the females its incidence may reach 50 per cent.; the commonest sites are the mammary gland and the lung. The important point, however, is that mice on all diets are about equally affected; no evidence has been found that the first diet protects against this disease or that the others predispose to it.

Work on the filter-passing viruses has been continued during the year, without, however, leading to any striking advance; the chief difficulty at the moment is to discover some method by which they can be grown in artificial culture. As regards canine distemper, it is now possible to immunise dogs successfully, but the methods at present in use can only be employed successfully in a specialised laboratory.

Applied Physiology.

J. A. Campbell has now completed his experiments on acclimatisation to low oxygen pressures. He found that this is due to the tissues, especially the heart muscle, becoming tolerant of the low oxygen pressure. Estimation of the tissue oxygen and carbon dioxide tensions, by injecting nitrogen into the tissues and then withdrawing samples for analysis, showed that the local oxygen tension remained low after acclimatisation. In the same way, exposure to increased oxygen pressures led to a marked rise in the oxygen tension in the tissues. It appears, then, that the tissue oxygen tensions depend directly upon that of the inspired air.

In conclusion, reference may be made to the work carried on by H. M. Vernon and his collaborators on industrial fatigue. A great variety of subjects has been investigated, including hours of work, accident causation, machine design, ventilation and heating, rest pauses and illumination. Practical application of the results obtained should lead to the greater comfort and efficiency of the industrial worker.

Association of Technical Institutions.

In the unavoidable absence of the president for 1928 (Sir Alfred Mond), Lord Riddell gave an address at the opening session of the annual general meeting of the Association of Technical Institutions, held at Stationers' Hall, London, on Feb. 24 and 25. Since he had been president of the Association during 1927, Lord Riddell was able to give some of the impressions of technical education he had gathered from his examination of its problems. He commented on the great work and scholarship of the staffs of the institutions: he noted the widespread recognition which is now being accorded to the liberal quality of technical education: he stressed the necessity of developing day classes. At present, he said, there are about 850,000 pupils in technical institutions; of these 750,000 attend evening classes. Yet when one considers the numbers of young persons in England and Wales between the ages of fourteen and twenty-five, it is obvious that 100,000 day pupils does not represent the maximum of day work which ought to be possible. Finally, Lord Riddell presented a vigorous defence of modern young people against what are practically perennial charges of slackness and deterioration. This defence, Lord Riddell said, was necessary and opportune, since Sir John Reith, of the British Broadcasting Corporation, had recently implied such charges. He had, however, asked Sir John to come and address the meeting.

Sir John Reith's short address was not only devoted to the points referred to by Lord Riddell. As an engineer, he criticised the present training of engineers, and made a plea that greater cultural qualities should be given in that training. It would appear, however, that Sir John's views concerning the cultural qualities he urges are not a little confused. To illustrate the engineer's lack of them he related a story. With a friend he ascended a steep road. When they reached the top a marvellous panorama of the countryside was unfolded to their view. Deeply moved by its beauty, Sir John turned to note the effect of it all upon his companion. The latter, however, appeared to ignore it. "Listen to that traction engine coming up the road," he said; "it is knocking abominably!" It may have been a disappointing remark, but it was not evidence that appreciation of beauty was lacking. There are obscenities of sound as well as of sight: John Masefield's "dirty British coaster with a salt-caked smoke-stack, butting through the Channel in the mad March days" may be different from the "stately Spanish galleon dipping through the tropics," but it possesses its own qualities of beauty.

Col. Ivor Curtis's paper on education in the Royal Air Force was the very interesting story of an educational experiment: an experiment which had to be made for a branch of the Service which was without tradition. A central problem was to overcome the scepticism of the Service and to make it a working partner. The experiment has succeeded. The nature of the Royal Air Force makes it essential that all work should lead to the development of individual resource. In connexion with the actual scheme as it now exists (one-third of the Royal Air Force is obtained through the apprenticeship scheme and two-thirds from men recruited after the age of eighteen), the success of libraries at scattered centres has been particularly marked.

In view of the present tendency to investigate the qualifications and examinations of builders and architects, papers on the training of the architect and on technical education for the building trades by Messrs. T. P. Bennett and F. E. Drury respectively were greatly appreciated.

The report of the Council for the year contained an excellent record of work done in connexion with the University of London Bill, Matriculation (University of London), libraries in technical institutions, Architects' Registration Bill, the Emmott and Malcolm committees on education and industry, and examinations for part-time students.

The Indian Science Congress.

The fifteenth session of the Indian Science Congress was held in Calcutta on Jan. 2, 1928. In the absence through illness of His Excellency the Viceroy, who had intended to preside at the inaugural meeting in the Senate House of the University on Jan. 2, the proceedings were opened by His Excellency Sir Stanley Jackson, the Governor of Bengal. This is the third time the Congress has been held in the second city of the Empire, the first occasion being in 1914, when the first meeting was held, the second in 1921. To commemorate the fact that Calcutta was the birthplace of the Congress, and to bring out the rapid growth of this movement, the original *Proceedings* of the 1914 meeting were reprinted and distributed to the members. In fourteen years the space taken in recording these proceedings has increased seventeen-fold.

It was fitting that Dr. J. L. Simonsen, one of the two originators of this movement and the man to whose self-sacrificing labours as honorary secretary the Science Congress owes its origin and steady growth, should have been elected president for this meeting. The difficulties in starting an organisation which required the co-operation of so many autonomous bodies, such as the universities, a number of research institutes, as well as the many independent Government departments which deal with applied science in a continent the size of India, were considerable. The task of steering an unofficial movement past the many difficulties which were encountered during the early years was still greater. For this piece of public service India owes a great debt to Dr. Simonsen. The Congress is now firmly established and fulfils a very useful function in providing an annual meeting ground for men of science in India and in breaking down the barriers imposed by distance, by race, and by that condition which, for want of a better word, may be described as departmentalism.

In his presidential address, Dr. Simonsen first gave a short history of the origin and progress of the Congress, and directed attention to the services rendered thereto by a number of distinguished men of science, among whom Sir Sidney Burrard and the late Sir Henry Hayden took a prominent place. The Asiatic Society of Bengal from the beginning also did much to foster the movement. Dr. Simonsen then dealt with the growth of the research spirit in the Indian universities, and passed on to the present academic standing of these bodies. While the former is in a satisfactory condition and shows definite signs of progress, the general academic standing of the universities of India is being steadily lowered. This latter manifestation was attributed partly to the fact that the control of these universities is now largely in the hands of laymen, and partly to the circumstance that a university degree in India is regarded as a stepping-stone to Government employ. Two reforms were advocated to meet the situation—the control of the curriculum and of the examinations should be placed in the hands of the professional staff; admission to the various Government departments should be based on Civil Service examinations conducted by an impartial authority. The last portion of the presidential address dealt with the importance of the study of natural products (see Nature, Feb. 11, p. 216).

Much useful work was accomplished in the various sectional meetings. Among the most successful was that of the Section of Mathematics and Physics, where as many as eighty-one papers were presented. In his address, Dr. J. de Graaf Hunter gave a sketch of the results of studies of the figure of the earth from the earliest times. A spheroid has been used latterly as a reference figure and the geoid has been exhibited in relation to it. By this means determinations of the spheroids which best fit the geoid in India and the United States have been made on the basis of isostasy and without. In the case of India, isostasy does not account for the geoidal anomalies, and large areas appear to have density anomalies larger than has recently been considered probable. The study of the geoid, combined with pendulum results, promises to yield further information about these crustal anomalies and may possess an industrial value.

The Section of Chemistry as usual attracted many members, and one hundred and forty-four papers were contributed. In his sectional address, Prof. S. S. Bhatnagar, of the University of Lahore, dealt with the progress of physico-chemical research in India and gave an interesting review of the past history and present position of this branch of science.

Another address which attracted a good deal of notice in the local press was that given by Dr. Michael P. West in the Section of Psychology. Two diametrically opposed types of educational psychology were contrasted, one emphasising the type, the other individual growth. Stress was laid on the need of a new type of institution which would give the child the means and opportunities for developing its own peculiar interests.

In the Section of Botany, Prof. M. O. Parthasarathy Iyengar gave an interesting review of various aspects of the study of algæ and emphasised the need for a handbook of Indian algæ as a means of stimulating research. This section, which was well attended and in which the discussions often reached a high level, reflected the great attention which has been given to botany in recent years by the Indian universities and the vastly improved teaching in this subject.

The other sections represented in the Congress were Agriculture, Anthropology, Zoology, and Geology. Owing to the recent session in Calcutta of the Far Eastern Association of Tropical Medicine, the Medical Section of the Indian Science Congress did not meet in 1928.

Three evening lectures, all of which were well attended, were given in the Senate House of the University: on radiations and their uses, by Prof. G. R. Paranjape; on applications of chemistry in modern warfare, by Prof. J. C. Ghosh; and on inheritance in plants and animals, by Prof. M. A. Sampathkumaran.

A very full programme of excursions was arranged by the local secretaries, and much hospitality was shown both by individuals and by public bodies. The University of Calcutta placed the Senate House and the other University buildings at the disposal of the Congress. Visits were arranged to the various research centres in Calcutta, such as the School of Tropical Medicine, the Bose Institute, and the Indian Museum.

University and Educational Intelligence.

Birmingham.—At the annual meeting of the Court of Governors, held on Founder's Day, it was announced that Mr. and the Hon. Mrs. Anstruther-Gough-Calthorpe had most generously made to the University a free gift of 40 acres of land adjoining the site of the University buildings at Edgbaston. It is hoped that this gift will allow of the provision of more playing fields in the near future and will give ample room for extension of the University for many years to come. It may be recalled that the site of the present buildings was also a gift of the Calthorpe family.

Cambridge.—Dr. N. J. T. M. Needham, Gonville and Caius College, has been appointed University demonstrator in biochemistry.

Sir J. J. Thomson gave the First Founder's Memorial Lecture at Girton College on Mar. 3 on the subject "Beyond the Electron."

London.—Mr. Bernard Ashmole, who, since 1925 has been Director of the British School at Rome, has been appointed as from Aug. 1 to the Yates chair of archæology tenable at University College.

Prof. Robert Robinson has been appointed as from Aug. 1 to the University chair of organic chemistry tenable at University College. Prof. Robinson studied at the University of Manchester, where he obtained the D.Sc. degree in 1910. He has occupied professorial chairs at Sydney, Liverpool, St. Andrews, as well as at Manchester, and has had considerable experience in industrial chemistry with the British Dyestuffs Corporation. He is the author of numerous papers mainly on the constitution of the colouring matters, brazilin and hæmatoxylin, on the isoquinoline alkaloids, and on the alkaloids gnoscopine, harmine, and strychnine.

Manchester.—Honorary degrees to be conferred on Founder's Day, May 23, include the following—LL.D.: Right Hon. Sir Alfred Mond, Bart.; D.Sc.: Prof. David Hilbert, professor of mathematics in the University of Gottingen, and Prof. C. T. R. Wilson, Jacksonian professor of natural philosophy, Cambridge. It is expected that Dr. Richard Willstätter, who was unable to be present last year, will receive the honorary degree of D.Sc. at the same ceremony.

Newcastle-on-Tyne.—At a meeting of Armstrong College Council held on Mar. 5, the resignation, as from Sept. 30, of Prof. J. J. Welch, professor of naval architecture since 1907, was accepted with regret.

The following new appointments were made as from Oct. 1: (1) Prof. T. H. Havelock, at present professor of applied mathematics in the College, to be professor of mathematics and director of the Department; (2) Dr. G. R. Goldsbrough, since 1919 lecturer in applied mathematics and reader in dynamical astronomy, to be professor of mathematics. Prof. Havelock, who is a graduate in science of the University of Durham and was for a time fellow of St. John's College, Cambridge, was appointed to the College as lecturer in applied mathematics in 1906, and promoted to the professorship in 1914. Since that date the Department of Mathematics (under Prof. Jessop) and the Department of Applied Mathematics (under Prof. Havelock) have been separate. Prof. Jessop having now reached the retiring age, the two departments will be combined and Prof. Havelock will take charge.

Oxford.—Prof. David M. Watson, Jodrell professor of zoology and comparative anatomy in University College, London, has consented to deliver the Romanes Lecture for 1928 in Oxford on May 4 at 5 P.M. The subject chosen is "Palæontology and the Origin of Man."

Calendar of Customs and Festivals.

March 11.

St. Sophronius.—Patriarch of Jerusalem at the time of its capture by Omar in A.D. 638. When the Mosque erected by Omar on the site of Solomon's temple fell in the night, the Jews told the Caliph that it would not stand until the True Cross was removed from Calvary, which the Caliph then ordered to be done. It is Sophronius who records that it was the custom at mid-Lent for the Cross to be taken out of its case to be reverenced.

March 12.

St. Paul of Leon, A.D. 573; son of a Welsh prince who migrated to Brittany at the age of sixteen, where he remained for the rest of his life, travelling about the country and finally being invested with the see of Leon, much against his will, by King Childeric. In art he is represented either with a bell or with a cruse of water and a loaf of bread, or driving a dragon into the sea to signify that he expelled the Druidical superstition out of Brittany. Popular legend incorporated in his life also credits him with the origin of megalithic monuments, for the avenue known by his name on an island in Morbihan is said to be composed of rude stones which grew from the pebbles with which his sister marked a path on the sands when the island was enlarged in answer to their prayers. The saint was the first to teach the people to domesticate wild bees and wild pigs. The bell, a familiar object in Christian antiquities of the Celtic period, is prominent in his legend. A bell was refused him by King Mark—in those days, it is said, seven bells were rung before each of the King's meals; but much later in life God sent him one "after many years of wishing and longing." The people called it by a special name because it was "green and oblong," obviously a bronze bell of a familiar type. In popular belief the bell is an effective protection against the spirits of evil and would be peculiarly appropriate to a missionary engaged in expelling Druidism with its magical practices from the country.

St. Gregory the Great, elected pope on the death of Pelagius II. in 590; one of the greatest figures in the Church, and responsible for the mission to Britain under St. Augustine which established Christianity in England. Many miraculous relations have been associated with him, of which the best known is that the Host visibly changed into the appearance of Christ enduring His passion in response to his prayers in order to convince a woman who disbelieved that the bread was flesh. On another occasion when disbelief was expressed in the efficacy of a cloth with which the relics of a saint had been wiped, as was then usual to save the relics from harm by touching, the cloth was cut at his behest, and blood poured from it as from the living body of the saint.

The processions at Rome on the festival of St. Mark, known as the 'Greater Litanies' or the 'Black Crosses,' were instituted by St. Gregory at a time of plague to avert the wrath of God from the city.

March 13.

St. Mochoemog, Abbot of Liathmor.—Of this Irish saint who lived in the middle of the seventh century, many marvellous happenings are related, but not least remarkable are the circumstances of his birth. His father, Beoan, married a beautiful damsel named Nessa of the race Nan-desi. In recompense for building, for his wife's sister, St. Ytha, a beautiful convent, he was promised a son; but before the promise could be fulfilled he was killed and decapitated in battle. His wife found his head and took it to her sister, reproaching her for the non-fulfilment of the promise. Nessa, following the instructions of St. Ytha, joined the head to the body and restored her husband to life. A son was born who was brought up by St. Ytha in the service of God, and later became the saint. The resemblance of the story of Beoan to incidents in Irish pagan legend needs no emphasis.

March 16.

St. Finian Lobhar, or the Leper; a descendant of Alild, king of Munster. A remarkable legend relates that St. Ruadanus had a miraculous tree in his cell which dropped a liquor into a bowl from nine o'clock to sunset that sufficed to dine him and his brotherhood every day. St. Finian visited him to persuade him to live like other people, and marked the tree with a cross so that the liquor ceased to flow. Ruadanus, on discovering what had happened, bade his servant fill a vessel with common water from a fountain. This he did, and it was at once changed into the marvellous liquor which had filled the bowl. Finally, St. Finian, after turning some of the liquor sent to him back into water, persuaded St. Ruadanus to live like other people and not to work any more miracles.

The emphasis in this story on the difference in mode of life suggests that it records not so much an encounter between two monks as a contest between a Christian missionary and a pagan magician, or even one of the fairy folk, *ruadh*, red, being one of the epithets most frequently associated with fairies.

March 17.

St. Patrick, born about 387.—His place of birth is uncertain, variously said to be Kilpatrick, Cornwall, Pembrokeshire, or Boulogne. At the age of sixteen he was carried off from Boulogne to Antrim by Niall of the Nine Hostages, returning home and entering the church six years later. He came back to Christianise Ireland in 432 and died in 465. Popular lives of the saint attribute to him the performance of many marvels. It is well known that he drove all snakes, toads, and noxious beasts out of Ireland; less familiar, that no spider will come near King's College, Cambridge, because it is built of Irish wood. It is not surprising to find him associated with the Celtic cross. He placed a cross at the head of every Christian buried outside a burial ground. There may also be a vague recollection of sun worship in the story of the fingers of St. Patrick affording a bright light when a horse was lost in the dark, and when at his death there was no night for twelve days. Tradition says that it was at a sun festival coinciding with Easter, after a solemn vigil when no fire had been lit for days, that St. Patrick preaching to the pagans made that symbolic use of the shamrock through which it became the national emblem worn on the saint's day at a time of universal rejoicing. But just as the saint's day may preserve the memory of the sun festival, the shamrock may possibly represent the traditional Celtic feeling for the group of three which is seen in the old Welsh triads, where the occurrence of groups of famous threes of a kind is celebrated endlessly.

Societies and Academies.

LONDON.

Royal Society, Mar. 1.—**A. E. H. Tutton**: (1) The hexahydrated double sulphates containing thallium. Thallium salts corresponding to the potassium, rubidium, cæsium, and ammonium salts of the isomorphous series $R_2M\left(\begin{smallmatrix}\mathrm{S}\\ \mathrm{Se}\end{smallmatrix}\mathrm{O}_4\right)_2 . 6\mathrm{H}_2\mathrm{O}$ have been prepared. Four of them are double sulphates containing thallium as the R-metal, and magnesium, ferrous iron, manganese, or copper as the M-metals; six are double selenates. (2) The hexahydrated double selenates containing thallium. The six salts are those in which R is thallium and the M-metal is magnesium, nickel, cobalt, ferrous iron, manganese, or copper. The results of the whole investigation (both papers) agree in showing that, as previously proved, potassium, rubidium, and cæsium salts of the great series invariably show crystal forms and properties which vary regularly with the atomic number of the alkali metal. The ammonium members, while showing no relation to atomic numbers or weights, resemble the corresponding rubidium salts containing the same M-metal so closely as to be practically iso-structural. Thallium salts invariably occupy a position well within the limits (as regards angles and constants) of potassium and cæsium salts. Thallium salts, however, have one strikingly outstanding property, that of very high optical refraction, occasionally exceeding even that of monobromonaphthalene and yet more so that of carbon disulphide.

W. H. J. Childs: The distribution of intensity in the band spectrum of helium: the band λ4650. Measurements of the intensity distribution in the helium band λ4650 (first of the main series) show that the predicted distribution is of the correct type, but agreement with observation is by no means complete. Notably the P and R' branches are much stronger, relative to the Q branch, than theory indicates. An expression of the form $i\epsilon^{-E/kT}$ where i is a linear function of j', is adequate to describe the observed distribution. As with many other bands, the temperature obtained by assuming that distribution of angular momentum is governed by the Boltzmann factor is much higher than the true temperature of the gas. In this case effective temperatures of approximately 750 A. and 1000 A. are found, depending on conditions of excitation. A higher temperature is obtained from the Q branch than from the P and R branches. Examination of Doppler width of band lines shows, however, that there is a distribution of translational velocities corresponding to true temperature.

M. C. Johnson: Studies in the behaviour of hydrogen and mercury at the electrode surfaces of spectrum tubes. The proportion of a hydrogen positive ray spectrum which is due to the neutralisation of protons is decreased by a temporary admission of mercury vapour. The accompanying domination of the spectrum by mercury can be delayed and weakened by the substitution of nickel for aluminium as the cathode material. The resistance at electrodes of different sensitivities to mercury contamination is not altered by that contamination if the tube is filled with hydrogen, but is sensitive to a change from hydrogen to air. Mercury is only liberated from a contaminated cathode during discharge. A solid mercury cathode can be made to disintegrate under bombardment in a manner different from its thermal evaporation, but the excessive disintegration product of the contaminated aluminium is from aluminium. The hypothesis is put forward that the increased cathode disintegration is the secondary effect of the removal of a surface layer of oxygen, allowing disintegration afterwards by ordinary proton bombardment, and allowing escape of hydrogen from the aluminium structure. The spectrum changes are then consequences of the mass and critical potentials of mercury.

W. E. Curtis: The structure of the band spectrum of helium. Details are given of three new helium bands which have the final electronic level $2P$ in common. Two of them are due to the vibrational transition $1 \rightarrow 1$, the initial electronic levels being $3S$ and $4S$. The other has an initial electronic level of effective quantum number 2·96, but its term type is uncertain. The rotation terms have been accurately evaluated for the three new bands and for three others previously described which also have the final level $2P$. The new evidence presented favours the view that the helium and hydrogen molecules are structurally similar.

H. A. Wilson: The Saha theory and the conductivity of flames containing alkali metal vapours. Noyes and Wilson have shown that the equilibrium constants for the reaction $M = M^+ + \epsilon$ (where M denotes atom of alkali metal and ϵ electron) can be deduced from measurements of the electrical conductivity of flames at about 2000° K, and that equilibrium constants so obtained agree approximately with those calculated by the Saha theory. This assumes that all salt sprayed into the flame is reduced to metal vapour and that all negative carriers are free electrons. It is now shown that these assumptions may be omitted without affecting the equation. Bennett's results on the conductivity of rubidium in flames give a value of the equilibrium constant nearly equal to that given by Saha's theory; Gouy's results on light emitted by sodium flames require the fraction of sodium reduced to metallic state to be independent of the concentration of sodium, and hence the fraction of ions which are electrons must be independent of concentration.

R. G. Lunnon: Fluid resistance to moving spheres. By timing the falls of metal spheres in water, through distances up to two metres, the resistance of a fluid at high speeds has been measured both for accelerated and for uniform motion. During accelerated motion, the resistance is increased in a regular way, which can be described approximately in terms of a carried mass, varying from one-half to twice the mass of the displaced fluid.

N. F. Mott: The solution of the wave equation for the scattering of particles by a Coulombian centre of force. The solution splits up into incident wave, representing on-coming electrons, and scattered wave; the quantum theory result agrees exactly with that of classical theory. The analysis is applicable to α- and to β-particles.

G. H. Briggs: A redetermination of the velocities of particles from radium-C, thorium-C and -C′. A redetermination by the magnetic deflexion method of $H\rho$ for α-particles from radium-C gives $3{\cdot}993 \times 10^5$ E.M. units. Using the theoretical value of e/m deduced from electrochemical data, the velocity is $1{\cdot}923 \times 10^9$ cm. per sec. The corresponding values found by Rutherford and Robinson were $3{\cdot}983 \times 10^5$ and $1{\cdot}922 \times 10^9$. Velocities for thorium-C and -C′ were found to be $1{\cdot}704 \times 10^9$ and $2{\cdot}053 \times 10^9$.

Physical Society, Feb. 10.—**Allan Ferguson** and **Eric J. Irons**: A simple graphic method for the determination of galvanometer and fluxmeter constants, with a note on the measurement of intense magnetic fields. The paper deals with methods for evaluating the principal construction constants of moving coil instruments by the graphical treatment of observations of logarithmic decrement and its variation with circuit resistance.—**J. C. Hudson**: The application of electrical resistance measurements to the study of the atmospheric corrosion of metals. The procedure is suited for quantitative field tests on the atmospheric corrosion of metals, and is based on the determination of the change produced on exposure in the electrical resistance of wire specimens. The method is capable of great accuracy. In the case of copper, the percentage resistance change due to corrosion is inversely proportional to the diameter of the wire; it is thus possible to use the method as an 'acceleration test' by conducting experiments on relatively thin wires, which are appreciably affected by corrosion within a few weeks.—**C. J. Smith**: On a method of constructing the caustic curve formed by refraction at a plane surface. The method depends on the properties of an ellipse which cuts the rays orthogonally.

Royal Meteorological Society, Feb. 15.—**L. F. Richardson** and **R. E. Munday**. Memoir No. 2 (published 1926): The single-layer problem in the atmosphere and the height-integral of pressure. Atmospheric tides are supposed to be such that a single vector suffices to specify the momentum of a whole column of air. Are ordinary weather disturbances of the same sort, or must each column be regarded as two or more layers moving independently? The answer to this question is extracted from the international collection of the records of registering balloons. It is found that Laplace's equations for *free* tidal oscillations are a very bad description of ordinary disturbances of the European atmosphere; in other words, the 'dynamic height' of the atmosphere is extremely variable.—**L. F. Richardson, D. Proctor**, and **R. C. Smith**. Memoir No. 4 (published 1926): The variance of upper wind and the accumulation of mass. Using the pilot-balloon observations made during the War, Durward's study of the variation of wind between two places at the same time is continued, by working up specially simultaneous observations at short distances (11 to 28·5 km.), and, surprisingly, the variation is found to be greater. Paired times at the same place are also investigated. The mathematical study of smooth functions accustoms us to the idea that accuracy is to be obtained by proceeding to the limit of smallness; but the wind seems not to possess the required kind of smoothness.—**J. Glasspoole**: The distribution over the British Isles of the average number of days with rain during each month of the year. While the east is the dry side of Great Britain and of Ireland, in the case of the number of days with rain the increase is more pronounced from the south-east to north-west of the British Isles. Actually, the average number varies from 150 along the Thames Estuary to 270 in the Outer Hebrides. There are only 10 days with rain on the average along the Thames Estuary in June, July, and September, and 26 in December in the north-west of Scotland and in the mountains of Kerry, Connemara, and Donegal. June is the month of fewest days with rain over the British Isles generally, namely 14, while December has most with 20. May also has less days with rain than either July or August, so that the popular call for early holidays is well supported by rainfall statistics. The amount of rain per rain-day is greater during the last six months of the year than the first six months, so that on the average May and June are again more favourable for holiday makers than July and August.

CAMBRIDGE.

Philosophical Society, Jan. 16.—**N. Feather** and **R. R. Nimmo**: The ionisation curve of an average α-particle. Systematic photometry of the track images from a cloud expansion chamber made possible the calculation of the variation of the light scattering power of an α-particle track over the last two centimetres of its length in standard air, and the variation of this quantity was finally identified with the variation of ionisation along the track. In air, helium, and hydrogen, the maximum ionising efficiency of the α-particle occurs when it possesses the velocity appropriate to the distances 3·0, 2·55, and 2·25 mm., respectively, from the end of its path in standard air.—**F. L. Arnot**: The interference of light in a wedge. When white light from a very narrow slit is reflected from a thin wedge, and then analysed in a spectroscope, interference bands are seen in the spectrum provided the edge of the wedge is parallel to the slit-source and to the slit of the spectroscope. Under certain conditions, the bands become clearer and more sharply defined as the width of the source is increased. These conditions are (1) that the light is incident on the wedge from the direction of its thick edge, and (2) that the distance between the wedge and the spectroscope has a certain value depending upon the angle of incidence of the light on the wedge.

PARIS.

Academy of Sciences, Jan. 30.—The president announced the death of Félix Henneguy.—**E. Goursat**: The rôle of the double characteristics in the problem of the deformation of surfaces.—**Hadamard**: The ergodic principle.—**A. Rateau**: The number of specific turns and the specific power of motor turbines.—**C. Sauvageau**: The Adelopycea of the Litosiphon.—**René Maire** and **Louis Emberger**: General view of our phytogeographical knowledge of Morocco: the regions, domains, and sectors.—**A. Khintchire**: The law of large numbers.—**S. A. Janczewski**: Homogeneous differential systems of the fourth order.—**Rolf Nevanlinna**: Complements to the theorems of unicity in the theory of meromorph functions.—**Paul Dumanois**: Concerning the theory of antidetonants. The hypothesis that antidetonants, such as lead tetraethyl, act by accelerating combustion is regarded as disproved by the experimental work of Moureu, Dufraisse, Chaux, Pigrot, Aubert and Villey, Egerton and Gates, Dumanois and Lafitte. The suggestion that antidetonants act by preventing the formation of peroxides (Moureu, Dufraisse, and Chaux) during compression is more in accord with the known facts.—**Pierre Dive**: The rotation round an axis of a heterogeneous fluid mass with ellipsoidal stratification.—**Émile Belot**: The origin of satellites with inverse revolution and the velocity of the primitive nebula.—**Nicolas Kryloff**: The variational algorithm and the fundamental problem of mathematical physics.—**J. Nageotte**: The study of myeline vesicles with the ultra-microscope.—**C.** and **H. Gutton**: The high frequency electrical discharge. The potential at which discharge (in hydrogen) takes place is measured as a function of the pressure, at wave-lengths of 3 to 5620 metres.—**J. Aicardi**: A new method of alinement by Hertzian waves. A description of a method of radio signalling by the use of which a ship or an aeroplane can follow a definite route during fog.—**Jean Thibaud**: Absorption discontinuities in the intermediate domain (K bands of carbon, nitrogen, and oxygen).—**G. Balasse**: Study of the continuous emission spectrum produced by the electrodeless discharge. The theory suggested in a previous communication leads to the conclusion that a continuous emission spectrum must be produced for all elements. This has already been proved experimentally for the elements cadmium, potassium, lead, calcium, mercury, and phosphorus, bismuth, sulphur, and iodine have now been added. Since these nine elements are distributed in five different columns of the periodic table, it may be considered that the continuous emission spectra produced by the electrodeless discharge is a general phenomenon extending to all elements.—**A. Couder**: The construction and trial of a telescope mirror of a particular form in Pyrex glass. The mirror is made in the form of a cylindrical tube closed at one end. The surface of the end is worked into a parabolic mirror of 136 cm. focus. The deformations produced by flexure are discussed: owing to the low coefficient of expansion of Pyrex glass, the thermal deformations have proved to be negligible.—**Y. Rocard** and **Ph. de Rothschild**: The absence of enlargement of spectral lines after reflection. It is concluded from the results of the experiments described that the enlargement of the lines by reflection on a mirror, the atoms of which possess thermal agitation, and might be expected to result in a considerable lowering of the order of limiting interference, does not exist.—**Néda Marinesco**: The molecular weight and association of chlorophyll in solution. The molecular weight determinations are based on the diffusion coefficient and the viscosity (Einstein equation). For sufficiently dilute solutions (less than 0·053 gram per litre) the molecular weight of chlorophyll is about 800, corresponding to the 817 for one atom of magnesium: for higher concentration there is evidence of the presence of associated molecules.—**G. Denigès**: The direct micro-estimation of the phosphoric ion by ceruleomolybdimetry in liquids from the animal organism, natural waters, fermented drinks, etc.—**Paul Dop** and **F. Duffas**: The water-bearing calyx of Clerodendron.—**S. S. Kharbush** and **Mlle. Panca Eftimiu**: The phenomena of chromatic reduction in the family of the Erysiphaceæ.—**Maurice Fontaine**: The reactions, at high pressures, of the pneumogastric of the frog immersed in a hypotonic solution.—**C. Motas**: A new Hydracarus collected at the Grand Lautien (Var).—**Y. Manouélian** and **J. Viala**: Nerve cells and the virulence of the suprarenal capsules.—**E. Roubaud**: The unfitness of *Plasmodium præcox* for development during the winter in *Anopheles maculipennis*, and its epidemiological consequences for northern Europe.

Geneva.

Society of Physics and Natural History, Dec. 15.—**Aimé Pictet** and **H. Vogel**: The synthesis of milk sugar. An equimolecular mixture of β-glucose and β-galactose heated to 175° C. in a vacuum gives lactose. The reaction takes place in two phases,

$$C_6H_{12}O_6 = C_6H_{10}O_5 + H_2O$$

$$\text{and } C_6H_{10}O_5 + C_6H_{12}O_6 = C_{12}H_{22}O_{11} \text{ (lactose).}$$

—**E. Briner** and **A. Morf**: Some new addition compounds of phenols with ammonia. Ammonia in the presence of β-naphthol, α-naphthol, α-oxyanthraquinone, salicylic acid, pyrocatechol, resorcinol, hydroquinone, or pyrogallol has given in each case one or two addition compounds corresponding to fixed conditions of temperature and pressure.—**E. Briner** and **G. Lunge**: The reactions between nitrogen peroxide and sulphur dioxide. These two substances in the liquid state give the compound $S_2O_9N_2$, containing six normal acid functions. It may be regarded as an anhydride of nitrosylsulphuric acid.—**R. Wavre**: The field of gravity in the interior of the planets.—**Raoul Pictet**: Integral transformation into motive power of the heat furnished to a gas. According to the author, who does not accept the second law of thermodynamics, it should be possible to convert the whole of the heat furnished to a gas into work.

Rome.

Royal National Academy of the Lincei, Nov. 20.—**G. Scorza**: Fundamental sub-groups of a group.—**L. Tonelli**: An observation on derivation by series.—**U. Cisotti**: The solenoidal character of Ricci's tensor for ternary forms.—**S. Franchi**: Tectonic enigmas in the mountains of Valdieri and along the valleys of Gesso, Stura, and Vermenagna.—**S. Baglioni** and **L. Settimj**: The nutritive value of the nitrogenous substances of certain types of preserved foods. Experimental investigations on albino rats. The nitrogenous matter contained in the dilute acid extract of cheese, dried stockfish, and dried edible fungi, and that contained in the part of cheese, stockfish, casein, and commercial hydrolysed casein which is insoluble in dilute acid, is capable not only of maintaining in equilibrium the nitrogen balance of albino rats, but also of allowing an accumulation of nitrogen and an increase in body-weight. The highest percentage increase in body-weight is obtained by means of a mixed diet composed of hydrolysed casein, the insoluble part of stockfish, and the soluble part of the fungi. The nitrogenous matter of that portion of the fungi which is insoluble in water is incapable of maintaining in equilibrium either the nitrogen balance or the weight of albino rats.—**D. Graffi**: Functions of vectorial variety.—**Cristina Eula** and **Odoardo Franceschi**: Projective study of surfaces.—**R. Caccioppoli**: A class of surfaces admitting of quadrature.—**U. Crudeli**: A category of stationary motions of (heavy) viscous liquids between two vertical cylindrical (round) tubes.—**A. Masotti**: The contact between lines of flux and lines of current in the motions of fluids.—**A. Rosenblatt**: Energy flux in the exceptional case of Kutta-Joukowski's theorem. — **B. Caldonazzo**: Viterbi motions and the triple orthogonal systems of surfaces determined by them.—**L. Fernandes**: The resolution of an absorption band regarded as common to praseodymium and neodymium. At a temperature approximating to that of liquid air, the line of wave-length 469 A. of the absorption spectra of praseodymium and neodymium is resolved into thin, sharp lines, the intensities and wave-lengths of these differing considerably with the two metals.—**A. Ferrari** and **A. Baroni**: The crystalline structure of the double cæsium cadmium chloride $CsCdCl_3$: considerations on the monometric structure of the type $A[BX_3]$. This salt exhibits a monometric lattice, with an elementary cell with the side 5·20 A. The ion $CdCl_3^-$ has dimensions lower than those given by the sum of the dimensions of the component ions Cd^{++} and Cl^-; this property appears to be general for complex ions. The crystallographic analogy between cadmium and mercury is emphasised by the identity in structure between the salts $CsCdCl_3$ and $CsHgCl_3$.—**G. Natta** and **M. Freri**: X-ray analysis and crystalline structure of cadmium–silver alloys. For the α-phase of the system cadmium–silver, representing solid solutions of cadmium (up to 44 atomic per cent.) in silver, the length of the side of the elementary cell varies linearly with the composition, increasing from the value 4·07 A. for pure silver to 4·14 A. for the alloy containing 31 atomic per cent. of cadmium. For the β-phase, corresponding with the compound AgCd and with solid solutions of cadmium in this, the photograms are of quite different appearance, the few lines present being arranged easily according to a body centred cubic lattice of the cæsium chloride type, and the calculated intensities agreeing well with the experimental values. Petrenko and Fedorow observed that at 460° the compound AgCd undergoes a transformation, which they interpreted as a decomposition of the unstable β-alloy into the neighbouring α- and γ-phases. The results now obtained show, however, that this consists of a polymorphic transformation, since all the lines of the photograms conform well with a hexagonal or rhombohedral lattice with the axial ratio 1·62; the side of the cell is $a = 3{\cdot}01$, and the elementary cell contains one molecule of AgCd, the calculated density being 9·57.—**G. Piccardi**: Relations between the ionisation potentials of the first and second order of homologous elements.—**R. Savelli**: Fruits of two varieties borne by the same plant.

FRIDAY, MARCH 9.

Royal Astronomical Society, at 5.—R. W. Gurney: Particles of High Velocity in the Chromosphere.—Dr. H. Jeffreys: Possible Tidal Effects on Accurate Time-keeping.—M. C. Johnson: Absorption by Nebulosity and the Temperature and Luminosity Sequences of Novæ.—Dr. H. Spencer Jones: The System of Procyon.

Physical Society (at Imperial College of Science), at 5.—Sir J. J. Thomson: Electrodeless Discharge through Gases (Guthrie Lecture).

Institute of Metals (Sheffield Local Section) (in Non-Ferrous Section, Applied Science Department, Sheffield University), at 7.30.—W. R. Barclay: Special Alloys in relation to the Corrosion Problem.

SATURDAY, MARCH 10.

Royal Institution of Great Britain, at 3.—Sir Ernest Rutherford: The Transformation of Matter (I.).

MONDAY, MARCH 12.

Royal Geographical Society (at Lowther Lodge), at 5.—T. Hay: Some Topography of the English Lakes.

Royal Society of Medicine (War Section), at 5.—Lieut.-Col. E. Cowell: The Pathology and Treatment of Traumatic Wound Shock.

Royal Institution of Great Britain, at 5.15.—Dr. E. Schrodinger: Wave Mechanics (III.).

British Psychological Society (Education Section) (at London Day Training College), at 6.—R. R. Dobson: Report of an Enquiry into the Attitude of Local Authorities towards Mental Tests.

Institution of Automobile Engineers (Birmingham Centre) (at Queen's Hotel, Birmingham), at 7.—G. L. Ensor: Notes on the Single Sleeve-Valve Principle.

Institution of Electrical Engineers (at Armstrong College, Newcastle-upon-Tyne), at 7.—T. N. Riley and T. R. Scott: Insulating Oils for High-Voltage Cables.

Ceramic Society (at North Staffordshire Technical College, Stoke-on-Trent), at 7.30.—J. Williamson: A New Type of Tunnel Kiln Suitable for the Firing of Pottery.

Institute of Metals (Scottish Local Section) (at 39 Elmbank Crescent, Glasgow), at 7.30.—Annual General Meeting.

Institute of Chemistry (Leeds Area Section) (at Leeds).—Dr. H. S. Houldsworth: The Expert Witness and the Law of Evidence.

Institution of Electrical Engineers (Western Centre) (at Swansea).

TUESDAY, MARCH 13.

Royal College of Physicians of London, at 5.—Dr. I. Bennett: Some Problems of Nephritis (Goulstonian Lectures) (I.).

Royal Institution of Great Britain, at 5.15.—Prof. J. S. Huxley: The Behaviour of Animals (IV.).

Institution of Petroleum Technologists (at Royal Society of Arts), at 5.30.—Lieut.-Col. S. J. M. Auld: The Natural Gas of South Persia, Process Development and Exploitation.

Illuminating Engineering Society (at Holophane, Ltd., Elverton Street, S.W.1), at 6.30.—Dr. S. English: The Manufacture and Properties of Glass and their Application in Illuminating Engineering.

Institute of Marine Engineers, at 6.30.—G. R. Hutchinson: Recent Developments in Propelling Equipment Practice of Reciprocating Engined Steamers.

Royal Photographic Society of Great Britain, at 7.—Annual General Meeting.

Institute of British Foundrymen (Lancashire Branch, Burnley Section) (at Burnley Municipal College), at 7.15.—W. H. Meadowcroft: Foundry Conditions.

Institution of Electrical Engineers (Scottish Centre) (at North British Station Hotel, Edinburgh), at 7.30.—F. H. Rosencrants: Practice and Progress in Combustion of Coal as applied to Steam Generation.

Quekett Microscopical Club, at 7.30.—T. H. Savory: Spiders and their Environment.

Pharmaceutical Society, at 8.—Dr. H. H. Dale: Some Reactions of Pharmacology on Pharmacy.

Royal Society of Medicine (Tropical Diseases, Psychiatry, Neurology, and Balneology Sections), at 8.30.—Special Discussion on Neuroses in the Tropics.

WEDNESDAY, MARCH 14.

Royal Institution of Great Britain, at 5.15.—Dr. E. Schrodinger: Wave Mechanics (IV.).

Royal Society of Medicine (Surgery: Sub-Section of Proctology), at 5.30.—C. Dukes: Demonstration of the Pathology of Obstruction due to Tumours of the Bowel —W B Gabriel Intestinal Obstruction following Colostomy.—Dr A F Hurst The Recognition, Cause, and Treatment of Megacolon in Adults —Sir Charles Gordon-Watson A Method of Removing Adenomata of the Sigmoid through the Rectum.

Institution of Civil Engineers (Students' Meeting), at 6 30 —H M. Pearson · The Belgian Railways

Institution of Engineers-in-Charge (at St Bride Institute, Bride Lane, E C 4), at 7 30 —G. A Hughes · Wells and Well Boring

Institute of Metals (Sheffield Local Section) (jointly with Kindred Societies) (in Department of Applied Science, Sheffield University), at 7 30.—Electrical Engineering Lecture

Royal Society of Arts, at 8 —H G Brown . The Lead Acid Cell . Its Place in Modern Industry

Lancaster Astronomical and Scientific Association (at Storey Institute, Lancaster), at 8 —Prof H E Armstrong . Sir Edward Frankland, a Great Lancastrian

Eugenics Society (at Royal Society), at 8 30.—Dr. W. R. K. Watson . Brixton Mental Tests

Institute of Chemistry (Manchester and District Section) (at Manchester) —F Twyman Absorption Spectrography and some of its Applications in Chemistry.

THURSDAY, March 15.

Royal Society, at 4 30 —Intense Magnetic Fields. Communications will be made by Sir Ernest Rutherford and Dr P Kapitza, and a general discussion will follow.—*To be read by title only*:—J. D Cockcroft The Design Coils for the Production of Strong Magnetic Fields —D. Jack: The Band Spectrum of Water Vapour —R d'E. Atkinson Statistical Experiments on the Motion of Electrons in Gases —Lord Rayleigh · The Light of the Night Sky its Intensity Variations when Analysed by Colour Filter III

Linnean Society of London, at 5.—Dr S W. Kemp. Whaling Researches and the Work of the *Discovery* Expedition.

Royal College of Physicians of London, at 5 —Dr. I. Bennett Some Problems of Nephritis (Goulstonian Lectures) (II)

Royal Institution of Great Britain at 5 15 —Dr J. J Fox Optics and Chemistry (II)

Institution of Mining and Metallurgy (at Geological Society), at 5 30.

Child-Study Society (at Royal Sanitary Institute), at 6 —Prof J. Dover Wilson The Literature of Childhood from Isaac Watts to De La Mare.

Institution of Electrical Engineers, at 6 —W T Townend Some Considerations of the Economics of Electric Power Production

Royal Aeronautical Society (at Royal Society of Arts), at 6.30 —Dr. Rudorf Testing of Materials used in Aircraft Construction.

Institute of Metals (London Local Section) (at 83 Pall Mall), at 7 30. —W Lambert High Tensile Bronze.

Chemical Society, at 8.—H. Burton and Prof C K. Ingold · Mobile-anion Tautomerism Part I. A Preliminary Study of the Conditions of Activation of the Three-carbon System, and a Discussion of the Results in Relation to the Modes of Addition to Conjugated Systems. —Prof. T. M. Lowry, C A H. MacConkey, and H. Burgess Studies of Dynamic Isomerism. Part XXVII The Absorption-spectra of Prototropic Compounds. No. 3046, Vol. 121]

Industrial Research Laboratories.[1]

THE National Research Council of the National Academy of Sciences, Washington, has recently published the third edition (revised and enlarged) of a bulletin on the industrial research laboratories of the United States, including consulting research laboratories. The original publication, compiled in 1920, listed about 300 industrial laboratories; the first revision, in August 1921, included 526 laboratories; and the present revision contains data for 1000 laboratories. The survey does not include laboratories connected with Federal, State, or municipal governments, or with educational institutions, and it is limited to the laboratories rather than organisations supporting research. It is claimed not that the present compilation represents a complete list of the industrial research laboratories, but that it probably gives a "fair survey of industrial research" in the United States. Under each entry there are given: the name and address of the company and address of the laboratory if different from that of the company; the name of the director of research and the number of his staff; and the chief lines of research work. In addition to the alphabetical list of laboratories, there are a subject classification and a geographical classification.

The value and quality of the information given in the bulletin must, of course, depend largely on the method of compilation. It is stated that all the information has been obtained directly by correspondence. Moreover, no investigation was made to ascertain the character of any laboratory listed nor the quality of the work done. *Questionnaires* were sent to about 1500 firms, and the information given is based mainly upon the replies received to these *questionnaires*. It will be realised that the answers supplied in this way must vary in quality and accuracy. The conscientious firm will be careful not to include, in its enumeration of research staff, employees who are little better than technical craftsmen engaged in routine testing, and will be scrupulous to distinguish between genuine industrial research and the mere checking of works products. On the other hand, the less conscientious firm, anxious to make some sort of a 'splash' in a comprehensive record of national research agencies, will be inclined to include employees who can only by a long stretch be brought into the category of research workers, and to look upon mere repetitive testing as being, in a sense, industrial research. Nothing is said in the bulletin as to whether the *questionnaire* sent out indicated the criteria by which a firm was to decide whether it had, or had not, a veritable industrial research laboratory, meet for inclusion in the list.

---

[1] *Bulletin of the National Research Council, No. 60:* Industrial Research Laboratories of the United States, including Consulting Research Laboratories. Third edition, revised and enlarged. Compiled by Clarence J. West and Ervye L. Risher. Pp. 153. (Washington D.C.: National Academy of Sciences.) 1 dollar.

Bearing in mind these qualifying considerations, we must, nevertheless, admit that the publication affords remarkable evidence of the variety and extent of the industrial research being prosecuted in the United States, the firms enumerated ranging from such a body as the Bell Telephone Laboratories, Incorporated, with its staff of 2000 full-time research workers, to firms claiming only a single research worker who—it is occasionally admitted—is engaged "intermittently" on research problems. One gets a picture—perhaps not more than a flashlight picture—of a thousand industrial laboratories engaged in the task of winning the scientific knowledge and elucidating the scientific principles involved in many hundreds of varied industries; and in devising ways of applying to industrial practice the science so acquired, so as to cheapen or improve existing materials, to find new materials, to discover new processes and, generally, to raise the level of production in quantity, quality, and variety, while lowering its cost. If we envisage this scientific work associated with the contemporaneous movement, organised on a national scale, for the elimination of waste, and with corresponding developments in business organisation, scientific management, advertising efficiency, and methods of distribution, we shall understand—without taking into account the favourable monetary position of the United States—what formidable competitors in international trade American firms and corporations as a whole must be.

A few salient features of the bulletin may be noticed. In glancing through it we meet, as we should expect to meet, abundant evidence of the provision made for industrial research by those industries which have, as it were, sprung from the loins of science—for example, the chemical, electrical, and optical industries. What is significant is the evidence of a growing application of scientific research to industries hitherto largely empirical, with little or no scientific tradition behind them—industries that, like Topsy, simply 'growed.' To take a few examples only, we find industrial research laboratories dealing with baking, flour and foods, canning and preserving, fruit and fruit products, building materials, fur products, laundering and milk. There are a few laboratories maintained by the co-operation of several firms in the same industry organised as research associations; but, for the most part, the laboratories enumerated are parts and parcels of the industrial organisations of individual firms and corporations. Their number is significant of the extent to which science is gaining domicile within the industrial units.

The Mellon Institute of Industrial Research, at the University of Pittsburgh, is in a class by itself. Its work is carried on under the Industrial Fellowship System of Robert Kennedy Duncan. Individual firms or groups of firms provide the funds for the maintenance of one or more industrial fellows whose full time is given to the investigation of technological problems that require protracted periods—a year or longer in each case—for their satisfactory solution. The industrial fellows at present comprise 79 chemists, 10 ceramists, 10 engineers, and 3 biologists, and they are engaged upon sixty different lines of scientific investigation.

It is probably true that the greater part of the scientific work done in these industrial research laboratories, taken as a whole, is directed to the immediate problems of the respective firms or industries; but, even so, it must involve some, perhaps much, fundamental research. In the laboratories of the larger firms or corporations a great deal of fundamental research—research in pure science—is deliberately planned and undertaken on broad lines, irrespective of any prospect of immediate industrial benefits, because it is realised that such scientific research is the fountain from which the streams of applied science must flow.

We need a similar compilation of industrial research laboratories for Great Britain, so that we may see in some measure how we stand. Are the individual industrial firms in this country calling in science to redress the balance of international competition? No doubt the big industrial corporations are devoting considerable expenditure and human effort to scientific investigation, and the modern tendency towards greater industrial aggregations, by the combination of smaller firms, will increase the facilities for more extensive scientific research. But a great area of British industry is occupied by small or medium-sized firms, directed by strongly individualistic owners, where the industrial units are too small to enable industrial research, on any adequate scale, to be carried on individually. Much has been done to provide the industrial research needed in this area by the establishment of the research associations formed under the ægis of the Department of Scientific and Industrial Research. These associations are like the research associations in the United States, in that they are financed on a co-operative basis, but they differ from the American associations in that they are partly financed by grants-in-aid from the Government and they are more numerous and cover a wider and more diversified industrial field. For this area of numerous and varied medium-sized or small firms, they constitute probably the only practicable scheme for securing the prosecution of scientific research in the closest association with industrial effort—for getting the relevant industries saturated with science—and their future existence and development is a matter of national concern.

The census of production, imperfect though it be, has already been of great industrial value in enabling us to appreciate our economic position. A most useful supplement to such a census would be the publication of a conspectus of all the industrial research laboratories in Great Britain, especially if it could be ensured that only laboratories and workers engaged in veritable industrial research were included. Such a return, though it might disturb our complacency, would be likely to quicken our sense of the leeway to be made up, in this matter of applying science to industry, if we are to meet in the open markets of the world our chief foreign competitors — notably the United States and Germany—on at least equal terms.

J. W. Williamson.

A Record of a Dying People.

The Arunta: a Study of a Stone Age People. By Sir Baldwin Spencer and the late F. J. Gillen. In two volumes. Vol. 1. Pp. xxviii + 390 + 87 plates. Vol. 2. Pp. xvi + 391-646 + 64 plates. (London: Macmillan and Co., Ltd., 1927.) 36*s*. net.

No anthropological book has had s[illegible]able a reception or given rise to such vo[illegible]inous discussions as "The Native Tribes of Central Australia," by Prof. Baldwin Spencer and F. J. Gillen, on its publication in 1899. Twenty-eight years later, Sir Baldwin Spencer has issued a new edition under the title of "The Arunta." The first edition was the result of several years' work; in the new edition is embodied the record of later investigations down to 1926, and thus the accounts of imperfect or partly understood native ceremonies and beliefs have been amplified and rectified. Comparison between the two editions will show, however, that a great deal has remained unchanged, because the earlier contained careful descriptions of what the authors actually observed, and being a record of facts, must remain valid for all time. It is in such matters that the anthropologist has the advantage over most scientific men, for observations in the field when made, as in the case of the Australian, on a vanishing people, cannot be repeated by future students, and therefore researches of this kind will never become out-of-date. The impossibility in many cases of subsequent checking of his statements thus imposes on the anthropological observer a grave responsibility. Sir Baldwin Spencer was a scientifically trained zoologist when he began to study the natives of Central Australia, and we can rely entirely on his account of what he witnessed. The late Mr. Gillen had for a long time gained the confidence of the natives and was thus an indispensable colleague.

The discussions alluded to above necessitated a reconsideration of certain interpretations and a new inquiry into some of the statements previously made and into the belief of the natives. Sir Baldwin has done his best to clear up these matters. Not long after the publication of the first edition, the investigations made by the late Rev. C. Strehlow were published in a series of papers in the *Veröffentlichungen aus dem Städtischen Völker-Museum*, Frankfurt-am-Main, and these were accepted as authoritative by German anthropologists, and most English students took them very seriously. The earlier parts were edited by the late M. F. von Leonhardi, who in the 'Vorrede' to the 1910 issue strongly supported Strehlow against his critics. Certain discrepancies between the observations of the German and English investigators have been ascribed in part to their working among different sections of the great Arunta tribe. It also seems that there were definite limitations attached to the researches of Strehlow, so that, despite his mastery of the language, he was unable to partake in personal experience of the ceremonial life of the natives which the lay investigators were able to obtain. It is, moreover, a common experience that for obvious reasons missionaries cannot always persuade natives to disclose their secret and sacred beliefs and practices. Sir Baldwin has discussed, in foot-notes and appendices, some of the points in which the two accounts varied or differed. We have, therefore, in this book the matured judgment of the author on subjects that required elucidation.

It will be noted that in the new book there has been a slight rearrangement of certain sections, and some have been enlarged, such as that on "Social Organisation," though in this section allusions to the social organisation of neighbouring tribes has been omitted. The earlier discussion following the account of "knocking out of teeth" has been greatly abbreviated, and the comparison with other tribes has been omitted, but, fortunately, references to the customs of neighbouring tribes are usually retained elsewhere. Attention should also be directed to the fact that there are a few alterations in the spelling of native words, or even in the words themselves. It will be necessary for all those who have made notes for lecture or other purposes to go over these carefully with the new book, as throughout this work there are many modifications, more especially in the account of religious beliefs. The description of the stone implements has been greatly enlarged and more fully illustrated, and improvements have been made in the parts dealing with material culture and decorative art. There are nearly twice as many illustrations in the new book as there were in the old, and so, being of excellent quality and carefully printed, they add very greatly to the value of the book.

As occurs elsewhere in Australia and also in parts of Melanesia, physical differences are said to characterise the two moieties; here one is supposed to have straight and the other curly hair (vol. 1, p. 42). Forty samples of hair were collected and given to Dr. O. W. Tiegs for examination; his report is reprinted in Appendix E, in which he says he cannot confirm the aboriginals' belief, though from blood tests on South Australian natives there is evidence to show that a mixture of 'blood' has occurred. "This suggests that the widespread idea of the aboriginal that he is composed of two distinct races, still recognisable by their straight and wavy hair, is a tradition which has descended from a past age, when a wavy- and a straight-haired race existed, and that these two races have now largely fused" (vol. 2, p. 599).

In the earlier discussions on the Arunta, emphasis was laid by some on their very primitive character; indeed, some regarded them as the most primitive of all people, and this in face of the elaborate ceremonies, complicated social system, and the fact that "the traditions of the tribe recognise four more or less distinct periods in the Alcheringa" ("The Native Tribes of Central Australia," p. 387). The periods and the cultural innovations which characterised them were also summarised (*l.c.* p. 421). The evidence in the new book confirms this. Except for a few objects of material culture, the Andamanese, to take but one people, are much 'lower' than the Arunta or any Australian tribe.

In the far distant Alchera time, a few superhuman beings called Nŭmbăkŭlla brought elements of culture to the Inapătua creatures (*i.e.* incomplete human beings), whom we may regard as being the very backward aboriginal population; these were made into men, doubtless through the instrumentality of initiation ceremonies. The culture-bearers brought the *churinga* and reorganised social relations. There is thus traditional evidence of cultural movements which ultimately affected the whole of Australia—just as in New Guinea and Melanesia we find analogous cultural drifts. Migrations of culture are due (1) in some cases simply to the borrowing of elements of culture from neighbours; (2) in others, there is a definite introduction of culture by means of a limited number of persons who appear to be more advanced members of the same race as the recipients, or at all events closely related; (3) in a few cases there is evidence that the immigrants belong to an alien race. In Australia, the evidence seems to point to the first and second of these alternatives, as it does in New Guinea as a whole. There is also good reason to believe, as indeed is most probable, that this cultural drift came from New Guinea.

Geology of the Alps.

(1) *The Structure of the Alps.* By Prof. Léon W. Collet. Pp. xii + 290 + 12 plates. (London: Edward Arnold and Co., 1927.) 16*s.* net.

(2) *Die Deckentheorie in den Alpen* (*Alpine Tektonik, 1905–1925*). Von Prof. Dr. Franz Heritsch. (Fortschritte der Geologie und Paläontologie, herausgegeben von Prof. Dr. W. Soergel, Band 6, Heft 17.) Pp. iv + 75-210. (Berlin: Gebrüder Borntraeger, 1927.) 8 gold marks.

N[illegible] least fascinating of the many aspects [illegible]lpine studies is that of the geological history and growth of the elevated region from which the peaks as we see them have been carved. With good cause has it been claimed that the synthesis of the Alps is that of the mountain-mass in general. In the two books before us the authors have set forth the latest views of Alpine tectonics, particularly those of recent developments of the theory of *nappes* or *Decken*. In the Alps, between two rigid massifs of rocks, folded and metamorphosed in Palæozoic and possibly pre-Palæozoic times, is found a zone of well-bedded Mesozoic and Cainozoic sediments. Movement of the southern massif towards the northern caused buckling in the intermediate region, and the folds thus developed were overturned and finally squeezed out and expelled north-westwards as great overlapping sheets (*nappes de recouvrement, Deckfalten*).

More than twenty of these nappes can be recognised: they lie one above another, folded and rippled in their upper portions, but drawn-out, sheared, and torn in their lower limbs. Different nappes may be folded with or may envelop one another. The later folds deform the older and, like waves, break and splash north-westwards over them. In places the upper nappes, by their forward movement, are supposed to have set in motion the lower and less extensive sheets. Where resistance to movement varied (as, for example, in the area between the Mont Blanc and Aar massifs), the nappes, retarded laterally, may swell forward into arcs or festoons of arcs, and exhibit fold 'virgation.' From the brow of a nappe in the north or north-east to its roots in the south or south-east, the translation of the rocks may amount to more than 100 km.

Such is the fascinating conception of the theory of nappes or Decken. In Prof. Collet's book, which will be welcomed as the first exposition in English of these views, Alpine problems are considered almost (if not exclusively) from the viewpoint outlined above. Prof. Heritsch's work, however, goes much farther than its title might suggest; it summarises the evidence for and against views of Alpine tectonics which seem irreconcilable.

(1) There is no question that Prof. Collet's book will serve a very useful purpose in attracting the interest of travellers to the geology of the Alps; students in universities and schools will doubtless also be grateful to him for his lucid treatment of a difficult subject. At the outset, the author introduces the reader to the fundamental conception of the Alpine geosynclines or large basins of deposition, and their intermediate geanticlines or ridges. The margins of the basins yielded the autochthonous sequences and the deeper parts supplied the rock-successions of nappes. These principles are applied to the elucidation of various regions in turn. In the Mont Blanc area the granite is thrust northwards over the sedimentary zone of Chamonix and is separated by it from the ancient mass of the Aiguilles Rouges. The Aar Massif and High Calcareous Alps, with their autochthonous and parautochthonous rocks (the latter term not being defined except by implication), are illustrated by excellent descriptions of the districts of Kandersteg and Grindelwald, of Jungfrau, Monch, etc.

These accounts are given in a form which will enable visitors to the Alps to search out the evidence for themselves, especially if they are also provided with the excellent geological guides of the Swiss Alpine Club; we cannot therefore grudge the space devoted to them, particularly as they embody the results of much of the excellent and arduous investigations of Prof. Collet himself. Some readers, however, may wish that the space occupied by 24 pages on the Jura Mountains had been at any rate in part devoted to the expansion of the account of the Glarus Alps or the wonderful Klippen (nappe-outliers) of the Pre-Alps of northern Switzerland.

The Pennine Nappes, the piling-up of which has produced the Valais Alps, are interpreted in the light of Argand's work, and are so described that geological study may be combined with climbing and sightseeing at such resorts as Arolla, Zermatt, and the Upper Engadine. Eastwards, the great half-window of the Swiss Alps is closed on the famous 'Rhine-line' from Constance to Chur, for the Aar massif and older nappes plunge beneath the later sheets which form the Eastern Alps (the Austrides of R. Staub). Prof. Collet makes a praiseworthy effort to render clear the succession and relationship of the nappes of the Eastern Alps, according to the view of Termier, Kober, R. Staub, and others, but the necessarily condensed form of the account and the absence of detailed locality-maps will render this section difficult for students.

Prof. Collet writes with such freshness and vigour that we fear the reader may forget that the Decken theory in its wider implications is but a theory. In a book of this size it is perhaps difficult for an author to separate evidence from speculation. It is a little tantalising, however, to be told, without being informed of the evidence, that the Alps provide "a great support to Wegener's theory" (p. 22), or that (p. 246) "We shall see, later on, that the higher Prealps . . . represent a small part of Africa resting on Europe." Unfortunately, Africa is not mentioned again in the book. True, it is postulated that the northward-drifting of Africa (or Gondwanaland) closed the geosyncline (the Tethys of Suess), the sediments of which were forced upwards and forwards to build the Alps, the underlying sima being injected as basic intrusions in the Pennine nappes. The existing Mediterranean area is then regarded by Argand and Staub as due to distension produced by the drift of Europe away from Africa. But this is hypothesis, albeit brilliant.

The extensive bibliographies form a valuable feature of the book. A glossary, with an explanation of the terms as ordinarily used in Britain, would also help non-geological readers.

(2) Prof. Heritsch's review of the progress of investigation of the Alps is a publication of an entirely different character. It is a compilation

certain to be of the utmost service to those who wish to undertake a serious study of Alpine tectonics and to appraise the evidence leading up to the different interpretations of the complicated structures. Its bibliographical details alone are of great value. Prof. Heritsch himself has done much original and valuable work in the Eastern Alps, but although he calls himself an opponent of the Decken theory so far as that region is concerned, he spares no trouble to set out the views of its various supporters, paying frequent tributes to the publications of Albert Heim, Rudolf Staub, and other exponents of it. He traces the history of Alpine investigation and the development of the 'mushroom,' overthrust and Decken theories. To make clear his later discussion he gives an admirable account of the terminology and rationale of the Decken theory. A brief description of the structure of the Swiss Alps forms a prelude to a comparison with the Eastern Alps. A detailed account of the tectonics of the latter and an exposition of the conflicting views constitutes the greater part of the book. Incidentally, the character of the famous 'window' of Hohe Tauern is discussed in some detail.

Finally, the age of the several phases of the mountain-building movements, the cause of the diastrophism and the difficulties of determining the age of the glyptogenetic stages, are set forth. Throughout the book the author insists on the view of the East Alpine geologists that the movements were not a unified and continuous series, but phases of crumplings separated by time-intervals. The present position in the study of Alpine tectonics may therefore be summarised by saying that, between the views of the extremists of the Swiss school on one hand and many of the Austro-Alpine geologists on the other, there is a great gulf fixed, no less deep and significant than the Tethys of Suess itself. P. G. H. Boswell.

The Electron, the α-Particle, and the X-Ray.

Handbuch der Physik. Herausgegeben von H. Geiger und Karl Scheel. Band 24: *Negative und positive Strahlen, zusammenhangende Materie.* Redigiert von H. Geiger. Pp xi + 604. (Berlin: Julius Springer, 1927.) 49·50 gold marks.

THIS important book is divided into six chapters, each of which is written by an authority on his subject; the whole is edited by Prof. Hans Geiger. Dr. Bothe gives an informed and comprehensive account of the work on the passage of electrons through matter, their velocity and ionising power, their absorption in and scattering by substances, and on the secondary rays to which the electrons give rise. The second chapter, by Prof Rüchardt and Prof. Baerwald, deals with the passage of canal-rays through gases and solid objects; special attention is directed to the importance of the Doppler effect in canal-rays. The editor is responsible for the chapter on the passage of α-particles through matter, a subject which in the hands of Sir Ernest Rutherford and his pupils has been one of the most revealing in modern physics. This chapter, which is an excellent account of all the physical properties of the α-particle, is perhaps the best in the book.

A chapter on the absorption of γ- and X-rays by matter, which one would expect to follow the first three, is not included in this work. Instead, the subject of absorption is dropped in favour of two chapters on the structure of matter as revealed by X-ray analysts. These chapters comprise nearly half the contents of the book The first, by Prof. Ewald, describes in detail experimental work, and covers the whole field of contemporary activity; the second, by Prof. Born and Dr. Bollnov, deals with the theoretical aspects of the structure of solid objects and includes a section on the thermodynamics of solid substances. These two chapters are without doubt the best description of the investigation of crystal structure by X-rays that has been penned. In the concluding chapter we are introduced to a third subject, that of the relation between the properties of simple chemical substances and their atomic and molecular structure; this is the work of Prof. Grimm.

The book should make a wide appeal to all physicists who wish to follow the extraordinarily interesting and varied work which has resulted from the discoveries of the electron and α-particle, and the methods of X-ray analysis in recent years. Indeed, all but the first chapter could be read with real profit by physical chemists also. Neither physicists nor chemists will find all of this book easy reading; the subjects discussed cannot of necessity be described in terms of simple ideas; but the different authors have done their best to make their subjects intelligible. They have not been content to extract from the literature the more important work and to leave it uncritically to the reader's notice, they have made a determined attempt to convey to the reader by words and diagrams what the best workers on the subject at the present time regard as most important.

Too many works of reference at the present time give experimental results without a description of the more important methods by which these results have been obtained. In this book, with its 374 illustrations, which, although never elaborate, are always adequate, the methods of investigation are fully described. In this respect, in its comprehensiveness, in the care which both contributors and editor have given to the various chapters, and in the printing, this book is in the best German manner. A. S. R.

Social Science.

(3) *The Foundations of Social Life.* By Prof. H. P. Fairchild. (Social Science Series.) Pp. vii + 287. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1927.) 13s. 6d. net.

(4) *The Science of Society.* By Prof. W. G. Sumner and Prof. A. G. Keller. (Published under the Auspices of the Sumner Club on the Foundation established in Memory of Philip Hamilton McMillan, of the Class of 1894, Yale College.) Vol. 1. Pp. xxxii + 734. Vol. 2. Pp. xxii + 735-1481. Vol. 3. Pp. xxi + 1483-2251. (New Haven: Yale University Press; London: Oxford University Press, 1927.) 18s. net each vol.

(1) "THE Task of Social Hygiene" was first published fifteen years ago. It very well deserves the place which it has won, and a new edition needs no recommendation here. There can be few books of that date dealing with social problems of the moment which on re-reading at the present time would not seem stale. But such is the breadth and sympathy of Mr. Ellis's treatment, so illuminating is his presentation, that the book fully maintains its freshness. Mr. Ellis must be counted among the most inspiring teachers of his time, and the next generation will be fortunate if it finds someone with his depth and variety of scientific knowledge and his diversity of gifts to review its problems.

(2) Mr. Ellis may be said to be concerned with the broad problem of the right use of our growing knowledge to 'make and remake life.' Prof. East, in "Heredity and Human Affairs," is concerned with the application of our rapidly increasing knowledge of one branch of biology to the betterment of human affairs, and he has written a very readable book on this theme. It need scarcely be said that his scientific credentials to discuss problems of heredity are unimpeachable. It appears further that, unlike some of his fellow workers, he does not abandon his scientific attitude when he touches social questions, and as a result he has produced as good a book on eugenics for the general reader as exists to-day.

(3) Prof. Fairchild, in "The Foundations of Social Life," has essayed a difficult task. He has felt the need for a treatment of certain fundamental facts with which in his opinion students of any social science should be acquainted, and has therefore attempted in a short book to sketch the biological characteristics of man, his reaction to the environment, the nature of society, and the possibilities of rational control. It may perhaps be doubted whether success in so small a compass is possible, but if the attempt is to be made, it would be difficult to improve the plan of the present work. The execution of the plan is not so satisfactory. The author tends to talk down to his readers and the phrasing is sometimes loose. We may sympathise with Prof. Fairchild's desire to broaden the student's interests and to lead him to see the relation of what is to be his own special line of study to other problems. But is this the way to do it? There is certainly a danger in beginning with what is of necessity a very sketchy and inexact treatment of vast problems.

(4) There is a certain impertinence in reviewing in a few hundred words a work in three volumes containing close upon a million words that has cost one of the two authors a quarter of a century's work and his colleague a great part of the last ten years of his life. It seems that the idea of the book took shape in 1899, and that Prof. Sumner's "Folkways," published in 1907, was a development of part of the original scheme. Having treated this section in a separate work, he returned to the main task. He died in 1910, and Prof. Keller, who had been associated with him for a great number of years, has now brought the task to a conclusion, though there remains a final volume containing a case-book, bibliography, and index. The volumes are a monument of painstaking labour. The authors have spared no trouble in their search for facts, and the amount of literature consulted is immense. They present ample evidence for their generalisations. But, nevertheless, the impression left is one of disappointment. Why is this?

Let us first give in their own words the authors' intention in this work.

"In general we seek the sense of societal customs and institutions. That means to us their expediency as adjustments in living, whether or not we can come to any conclusion as to their origin. Nor do we regard it as enough merely to exhibit them as adjustments, so proved because of their survival; we hope to show also how and to what adjustment has been made."

The arrangement of the book is to describe and discuss customs and institutions classed in the following manner: (1) those having to do with self-maintenance, including (*a*) industrial organisation, (*b*) property, (*c*) regulative organisation, and (*d*) religion; (2) those having to do with self-perpetuation, including marriage and the family, and those having to do with self-gratification. The authors embark upon their immense labour with this programme and carry it through with devotion in some million words. But it fails to grip. The reader feels out for a guiding thread to lead him through the maze. There is no thread such as a truly scientific or purely descriptive treatment would have provided. The authors assume adaptation. They treat groups of customs and institutions as adaptations. They move a little way back and a little way forward by means of generalisations as they deal with each group, and then they pass on.

In many ways the treatment is reminiscent of Herbert Spencer's sociology, though the use of facts and the avoidance of grandiose generalisations render the present authors' work greatly superior. Is not the fundamental mistake this clinging to the conception of adaptation? Unless it is analysed, it is a truism of little value. In a sense every institution shows adaptation. But when the term is analysed it is found to cover many different conditions. Without analysis it is a vague and unsatisfactory conception. Upon analysis it leads to problems that demand a treatment quite other than that given in this book. Furthermore, however scientific may be the attitude of the authors in their reliance upon facts and their freedom from preconceived theory, no truly scientific treatment can begin from such a starting-point.

Thus we are led to regard the plan as misconceived. Nevertheless, the book is a mine of accurate information, and in it other students can dig. But they will not dig with profit unless they study method. Methodology in social science is the most urgent study in this field to-day.

Our Bookshelf.

The Natural History of Wicken Fen. Edited by Prof. J. Stanley Gardiner. Part 4. Pp. 267-383 + plates 7-9. (Cambridge: Bowes and Bowes, 1928.) 6*s*. net.

INCLUDED in this part are an article by the editor on Wicken Fen, and accounts of the fossil vertebrates, protozoa, planarians, cladocera, copepoda, diplopoda and chilopoda, and insects—Collembola, Coleoptera, Hemiptera-Heteroptera (Part II.), Orthoptera, Neuroptera, and sawflies. For many of the species recorded notes are added on the biology and ecology. In the account of the Coleoptera a list is given of the species which occurred in the fen districts of Cambridgeshire before 1854, but which are now not taken (26 spp.) or are less readily found, and another list of species which are now taken but were never recorded by the old collectors. Mr. Lowndes records that the same species of copepods are found living under the most varied conditions and in widely separated districts, but that these individuals do not exhibit greater differences than do those that live in any single pond. The *p*H was found not to have any direct influence on *Cyclops languidus*—a result differing from that reached by Labbé.

Prof. Stanley Gardiner emphasises the interest of Wicken Sedge Fen as an area that has not only never been cultivated, but also has never been deliberately drained, and thus constitutes a real bit of the old fenland. Except for bush growth, the Sedge Fen is much as Ray knew it in 1660, but some plants common then are rare now. Prof. Gardiner rightly claims that Wicken Fen is not only a "place of historic interest and of natural beauty," but also is the one place from which the history of the changes in the fauna and flora of the wet lands of England can be deduced with reasonable exactness. We congratulate him and his co-workers on these further results of their investigations, which are not only of great interest in themselves, but will also afford trustworthy information to our successors for comparison with conditions in their time.

Ministry of Agriculture and Fisheries. Fishery Investigations. Series 2, Vol. 9, No. 2, 1926. *Plaice-egg Production in 1920–21, treated as a Statistical Problem, with Comparison between the Data from 1911, 1914 and 1921.* H. J. Buchanan-Wollaston. Pp. 36 + 11 charts. (London: H.M. Stationery Office, 1926.) 8*s*. 6*d*. net.

QUANTITATIVE studies of living organisms in their natural habitats have a biological and mathematical interest far beyond the technical purposes for which they are usually made. The study of plaice-egg productions treated as a statistical problem by H. J. Buchanan-Wollaston affords a good example both of the interest and of the difficulties of such research. The report deals with egg counts of samples taken with the Hensen net in 1920–21, and comparison of the egg distributions inferred from these and earlier methods for 1911, 1914 and 1921. The mathematical methods are explained in a series of interesting appendices. These methods have a somewhat home-made appearance, and should not yet be regarded as standardised. Applied intelligently, and with a constant effort to keep in touch with the realities to be represented, they seem well suited to the immediate problem.

The statistical terminology is not always happy; terms like 'datum solid' used when 'frequency surface' seems to be intended, tend to obscure the essential contrast between *data* and *quæsita*. Much mathematical work will evidently be necessary before an adequate procedure is evolved, since the observations are necessarily sparse and are not simultaneous. The reviewer would judge that the full value of the observations will not be made available until the distribution problems involved are treated by methods of fitting rather than by methods of interpolation. R. A. F.

A Course of Modern Analysis: an Introduction to the General Theory of Infinite Processes and of Analytic Functions; with an Account of the Principal Transcendental Functions. By Prof. E. T. Whittaker and Prof. G. N. Watson. Fourth edition. Pp. vi + 608. (Cambridge: At the University Press, 1927.) 40*s*. net.

WITH the exception of certain corrections and additions, the fourth edition of this comprehensive work differs in no material respect from the third edition published in 1920. "Whittaker and Watson" has entered and held the field as the standard book of reference in English on the applications of analysis to the transcendental functions. This end has been successfully achieved by following the sensible course of explaining the methods of modern analysis in the first part of the book and then proceeding to a detailed discussion of the transcendental functions, unhampered by the necessity of continually proving new theorems for special applications. In this way the authors have succeeded in being rigorous without imposing on the reader the mass of detail which so often tends to make a rigorous demonstration tedious.

The book is admirably printed. The only faults which have been noticed are the omission of the upper and lower bar in the definitions of the 'upper' and 'lower' Riemann Integral (§ 4·11) and the omission of the line in the fraction on the right of the first identity in § 13·14. These are insignificant defects in a fine work which makes accessible a continuous account of methods recorded in a scattered series of memoirs. L. M. M.-T.

Blut und blutbildende Organe menschlicher Embryonen. By Dr. W. Knoll. (Denkschriften der Schweizerischen Naturforschenden Gesellschaft, Band 64, Abl. 1.) Pp. ii + 81 + 9 Tafeln. (Zürich: Gebr. Fretz A.-G., 1927.) n.p.

OPPORTUNITIES for the examination of fresh human tissues are of such rare occurrence that the present monograph will be greeted with interest by cytologists and medical hæmatologists. Dr. Knoll has been fortunate enough to collect human embryos in a living condition by surgical removal of the uterine contents through an abdominal incision, in twenty-eight interrupted pregnancies. He has undertaken a detailed examination of the various cellular structures in human embryonic blood, not only in permanent sections of the rapidly fixed embryo, but also in blood films prepared by the more modern hæmatological methods; especially interesting is the examination of fresh embryonic cells in hirundinised plasma. The physical characters and staining affinity of the various types of cells are analysed and also the oxidase reaction studied. Dr. Knoll's technique is presented in detail; for the oxidase reaction he uses a mixture of 1 per cent. α-naphthol in normal saline and 1 per cent. di-methyl-para-phenylene-diamine base.

The work is well illustrated and contains nine magnificently reproduced plates in colour presenting the details of the blood cells and stages in their development.

Coup d'œil sur la théorie des déterminants supérieurs dans son état actuel. Par Maurice Lecat. Pp. viii + 100. (Bruxelles: Maurice Lamertin, 1927.) 16 francs.

THE matrix in n-dimensions was originated by Cayley and Sylvester. It is quite possible that this purely algebraic conception may find a physical application in space of more than two dimensions. The contributions of M. Lecat to our knowledge of this subject are many, and the present summary is a forerunner of a treatise in three volumes to be published shortly, in which the original researches of the author will be more fully treated. The symbol of Kronecker which figures largely in the exposition is not defined. It may help the reader to note that this symbol $\delta_{i,j}$ is equal to unity if $i = j$ and is zero if $i \neq j$.

Physics for School Certificate (Heat, Light and Sound): a Revision Course. By W. Littler. Pp. 231. (Exeter: A. Wheaton and Co., Ltd., 1927.) 3*s*.

THIS is frankly a revision course. It contains the information required by the examiners in a reasonably small compass, and should prove useful in any school in which the chief object of including physics in the curriculum is to provide another subject for the school certificate examination. That there is a demand for such books is a serious criticism of the relative functions of schools and examinations.

Examen des différentes méthodes employées pour résoudre les problèmes de géométrie. Par G. Lamé. Pp. xii + 124 + 2 planches. (Paris: J. Hermann, n.d.) 21 francs.

A SIMPLE reprint, without introduction or notes, of an early work on algebraic geometry, first published at Paris in 1818. It is important historically as being the first book in which it was remarked that all curves (or surfaces) of order n which pass through the points common to two, $f = 0$ and $g = 0$, of this order, are represented by equations of the form $f + \lambda g = 0$.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Origin of the Nebulium Spectrum.

IN a letter to NATURE of Oct. 1, 1927, p. 473, Mr. Bowen has announced the very interesting relationship that some of the lines of unknown origin which are found in the nebulæ and in the Wolf-Rayet stars and were so long attributed to a hypothetical element nebulium, are really due to ionised light elements like O^{++}, N^{++}, O^{+}, N^{+} . . . ; they do not arise from the transitions usually allowed, but are due to transitions which are usually prohibited. Prof. A. Fowler has also lent his support to this hypothesis. The object of this note is to discuss the nature of these transitions.

Mr. Bowen finds that the following well-known trio of nebulium lines are due to O^{++}, and due to transitions shown below:

5006·84 . . . . . $^3P_2 - {}^1\bar{D}_2$
4958·91 . . . . . $^3P_1 - {}^1\bar{D}_2$
4363 21 . . . . . $^3P_1 - {}^1\bar{S}_0$

The structure diagram of O^{++} is shown below:

$$\begin{array}{l} O^{++} \ldots 2K\ 2L_1\ L_2 \\ \qquad\qquad\qquad M_1 \longrightarrow M_2 \longrightarrow M_3. \end{array}$$

$2L_2(p^2)$ gives us $^3P_{0\,1\,2}$, $^1\bar{D}_2$, $^1\bar{S}_0$.

All other four-valence elements, namely, C, N^{+}, O^{++}, . . . and C, Si, Ge, Sn, Pb have similar ground levels due to the electron-configuration p^2, that is, two electrons in *p*- (or *L*) orbits. The lines arise from transitions between metastable levels as pointed out by Bowen. It is interesting to note that though such transitions are not found in the spectra of light elements, they are of frequent occurrence in the spectra of heavy elements. In the spectrum of Pb, which is analogous to that of O^{++}, the values of the fundamental levels are

$^3P_0$	$^3P_1$	$^3P_2$	$^1\bar{D}_2$	$^1\bar{S}_0$
59821	52004	49173	38365	30355

Dr. Sur (*Phil. Mag.*, vol. 2, p. 623; 1926) in this laboratory found that the following lines exactly analogous to the above-mentioned nebulium lines are obtained in the heavy arc of lead. They are not present in the usual arc:

$$^3P_1 - {}^1\bar{D}_2 = \nu 13637, \quad \lambda = 7330 \text{ A.}$$
$$^3P_1 - {}^1\bar{S}_0 = \nu 21649, \quad \lambda = 4618 \text{ A.}$$

Other elements of the same group, namely, C, Si, Ge, Sn, can theoretically give similar lines, as the following Table shows, but a scrutiny of the existing literature shows that they have not yet been obtained. Whether they can be obtained in the heavy arc is yet to be seen.

$^3P_1 - {}^1\bar{S}_0$ for	
C	?
Si	ν15317
Ge	ν15810
Sn	ν19101

Let us now consider the nature of violation of the selection principle. I have shown that in the case of complex spectra the selection principle can best be explained not in terms of the different quantum numbers, but in terms of *electron transition*. Thus $pp \longrightarrow ps$ or $pp \longrightarrow pd$ transitions are allowed (one electron changing from the *p*-orbit to the *s*-orbit, or the *d*-orbit, corresponding to $\Delta k = \pm 1$ where k = azimuthal quantum number), but $pp \longrightarrow pp$ transitions are not allowed ($\Delta k = 0$). In terms of the structure diagram, this means that only those transitions are allowed in which the total number of electron transitions is odd. Hence the transition involved in the origin of the nebulium lines really violates the selection principle $\Delta k = \pm 1$; we have here $\Delta k = 0$, and in addition $\Delta n = 0$ (change of total quantum number $n = 0$).

It is well known from the experiments of Koch on helium and other subsequent experiments, as well as from theoretical considerations, that such violations take place when the region where the spectrum is produced is traversed by a big electric field, or in regions where the free charge density is high. In heavy elements, the principle is easily violated, because the central atomic field deviates largely from the radial. A big external electric field, or free electric charges, would help the process, where such internal fields are not present, as in light elements, or are insufficient. Such, in fact, is the interpretation to be put on Dr. Sur's results. Similarly, in other heavy elements, namely, Bi, Th, Au, prohibited transitions of this type are very frequent.

Bowen's interpretation of the nebulium lines as being due to prohibited transitions in light elements therefore implies that unusually big electric fields are present in nebulæ and Wolf-Rayet stars. This can be explained, because, owing to the extremely high temperature, matter must be in a very highly ionised state, and large fluctuations of electrical density, owing to accumulation of charges of one sign, must be very frequent. Bowen further finds that besides these lines, lines due to the transitions $L_2M_1 \longrightarrow L_2M_2$ and $L_2M_2 \longleftarrow L_2M_3$ of O^{++} are obtained in these stars. The fact that the electron, while returning from the higher excited group of orbits (due to L_2M_2), appears to linger too long in the less stable $^1D_2$ of the L_2L_2 combination, is to be attributed to this big electric field. Fluorescence of Mercury Vapour.

AN experiment with a double bulb of quartz containing mercury *in vacuo* and heated to a constant temperature, which showed fluorescence under illumination by the light of an aluminium spark only when one of the bulbs was cooled by an air blast, has been cited by one of us as proof that only distilling mercury vapour exhibits the phenomenon. This has been denied by Niewodniczanski, who obtained brilliant fluorescence in stagnant vapour.

We have re-examined the matter and find that the effects observed with the double bulb are due to traces of water vapour, the distillation carrying them over into the cooler bulb and leaving only pure mercury vapour in the warmer one. We have prepared bulbs which could be made to fluoresce in either way. A double bulb fairly well degassed by long heating and pumping, when sealed from the pump, shows brilliant fluorescence at constant temperature; if superheated locally with a flame for a few minutes, it will be found to fluoresce only when one bulb is cooled and distillation started. If now it is subjected to an electrodeless discharge by placing it between the metal plates of a high frequency oscillator (λ = 2·5 metres), in the course of ten or fifteen minutes the discharge becomes very feeble and the bulb is now found to be in its original condition, showing fluorescence in the absence of distillation. The electrical discharge appears to have driven the water vapour back into the quartz.

Niewodniczanski also reported that the 4358 arc line of mercury appeared on his photograph with excitation by the aluminium spark, but no other mercury lines. This we find due to the fact that his spectrograph was of too low dispersion.

We find practically all of the brighter arc lines, at least in the violet and ultra-violet, and they appear to result from two stage absorption as they vary in intensity with the *square* of the intensity of the exciting light, as shown by the wire-gauze test recently described by one of us in this journal.

Lord Rayleigh has found that the disappearance of the fluorescence by superheating, which was observed by one of us many years ago, holds only for the visible band in the blue-green region. The ultra-violet band remains. The band spectrum in this case was excited electrically.

We find that, with aluminium spark excitation, superheating the vapour at constant density destroys the blue-green band and *enhances* the ultra-violet band enormously (possibly tenfold). The arc lines which appear under this excitation are also greatly enhanced by the superheating. We are now using moving streams of mercury vapour to study the time relations of these processes.

Ultra-Violet Microscopy.

IN preparation for giving a course of instruction in ultra-violet microscopy, I have had occasion to study some of the incidental problems in this subject. One of the most troublesome was the provision of a satisfactory immersion fluid, which has hitherto consisted of a mixture of glycerine and water adjusted to give homogeneous immersion for the fused quartz system at $\lambda = 0{\cdot}275\mu$. This mixture is strongly hygroscopic, and the absorption of water by the film of liquid between the objective and slide causes a gradual change of focus sometimes noticeable in a few minutes. Moreover, in the process of changing objectives, a necessary part of the present technique developed by Barnard, some of the liquid becomes smeared on the slide, where it can readily absorb water and thus contaminate the liquid on the next objective inserted in position. A 'ropy' layer of liquid appears extremely likely, and this must constitute a serious drawback and a source of uncertainty.

I have lately been able to overcome this difficulty. By means of a recently designed refractometer, I have been able to measure the ultra-violet refractive indices of cane-sugar solutions in thin films, although the liquids are sufficiently absorbent to preclude a satisfactory measurement with a hollow prism for wave-lengths which are *shorter* than the region of $\lambda = 0{\cdot}275\mu$. By interpolation from the results, it was found that a cane-sugar solution having a refractive index for sodium light $n_D = 1{\cdot}4516$ would have the required refractive index (1·4961) for the ultra-violet. Glycerine and water has to be adjusted to $n_D = 1{\cdot}4530$. These figures are approximately correct for 18° C. An Abbe refractometer is convenient in practice.

Control experiments were made by adjusting cane-sugar and glycerine solutions to the same visual refractive index and measuring the refractive index after thorough mixing; this was found to be the same within the probable error of experimental conditions. Although there are indications which would make closer investigations desirable, we may assume a zero change for the present purposes.

Solutions of cane-sugar and glycerine adjusted to the figures given above should possess the same refractive index for the ultra-violet. 10 c.c. of glycerine solution was placed in each of four stoppered tubes to which 1, 1·5, 2·0, 2·5 c.c. of cane-sugar solution respectively were added and thoroughly mixed. The liquids containing least sugar were found to be still hygroscopic, but that with most sugar was found to evaporate very slowly; all such mixtures will, on exposure to the air, absorb or evaporate until equilibrium is reached. Thus on one day the following figures were found:

Proportion of sugar . .	1	1·5	2·0	2·5
Original n_D of mixture .	1·4529	1·4528	1·4528	1·4527
Equilibrium, n_D	1·4497	1·4509	1·4527	1·4540

It is clear that the liquid with its refractive index at 1·4527 is still practically at the strength which gives homogeneous immersion for fused quartz; on another day, another liquid might be nearer; it will be advantageous to have more steps in the series. The small proportion of sugar has not been found to absorb the ultra-violet sufficiently to render its use a drawback in the slightest degree at $\lambda = 0{\cdot}275\mu$.

With such a number of mixtures constantly exposed in shallow flat open dishes, it is possible, then, to select in a few minutes a liquid which will have for the time being a practically constant refractive index, and so obtain all the advantages which have already been hinted at. To illustrate the utility of the method, an inspection should be made of the ultra-violet photograph, Fig. 1, which was taken after the apparatus had been set up and focused with the quartz lens, *and then left for more than 26 hours*; one portion of the field was then *still* in critical focus; central focus was obtained by relative displacement of the objective and stage through 0 6μ only.

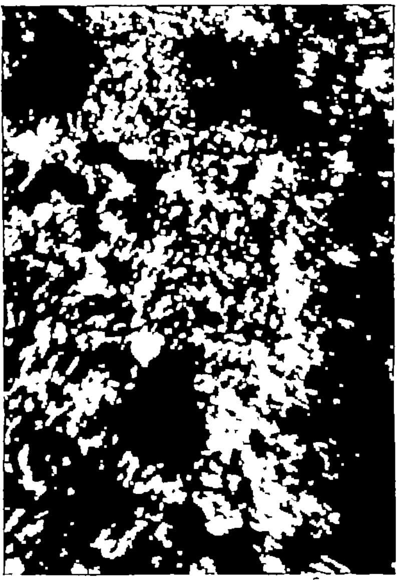

FIG. 1.—Chemically deposited silver film by transmitted light. ×3200. Image given by quartz monochromat using λ0 275μ.

The optical homogeneity of the liquid contributes materially to the possibility of high resolution. This photograph was taken with an original magnification of 800, and enlarged up to 3200. Every resolvable detail should thus be clearly visible to unaided vision. This image is better than any we have been able to obtain of the same object using an apochromat (N.A. 1·3) and blue light ($\lambda = 0·45\mu$), but there are reasons for thinking that the performance can be still further improved.

The fused quartz objective N.A. 1·20 was made by Messrs. R. J. Beck, Ltd., from material specially selected by thorough interferometric tests in the Technical Optics Laboratory; the design of the objective is due to Mr. R. J. Bracey, of the British Scientific Instrument Research Association. So far as the work has been successful up to the present, it is owing in no small measure to the skill and thoroughness of Mr. B. K. Johnson, who carried out the difficult refractometry necessary in the attainment of this new type of stabilised immersion liquid for the ultra-violet, and has also taken the greatest pains in the difficult initial adjustments of the microscopic apparatus.

The Pressures developed in Gaseous Explosions.

In the current issue of the *Journal of the Chemical Society* (Jan 1928), Dr. G. B. Maxwell and Prof. R. V. Wheeler have published a paper entitled "The Pressures produced on Inflammation of Mixtures of (*a*) Carbon Monoxide and Air, and (*b*) Hydrogen and Air in a Closed Vessel." From their carbon monoxide–air results they deduce the dissociation of carbon dioxide and offer some criticism of Fenning and Tizard's recent work (*Proc. Roy. Soc.*, A, **115**, 318; 1927). One of us has already written a criticism of Fenning and Tizard's paper (see Nature, July 30, 1927), and we have nothing to add to the views offered in that letter, except to express the opinion that dissociation in a gaseous mixture undergoing combustion is probably very different from that in a gas heated by external means. We note with interest that the Sheffield school now recognises the reality of incomplete combustion at the moment of maximum pressure, at any rate in carbon monoxide–air explosions.

Messrs. Maxwell and Wheeler use their hydrogen–air explosions for the purpose of calculating the specific heat of steam, and they show that in explosions in which there is excess hydrogen present, so that dissociation is presumably negligible, the calculated mean specific heat (15°-*t*°) does not vary much between 15°-1400° and 15°-2120° C. They infer from this that the specific heat of steam does not increase over the range of 1400° to 2120° C., but it is not probable that this inference will receive much support.

It so happens that we have been engaged on this problem for some considerable time, and while we are disinclined to accept the absolute values as determined by Maxwell and Wheeler, our results suggest that the *apparent* specific heat, as calculated from explosions with excess hydrogen, does not vary greatly over a wide range of maximum temperatures. We believe that we have experimental evidence to show that these peculiar results are due to incomplete combustion of varying extent.

The method which we originally adopted was that of varying the proportion of hydrogen to air, using 'airs' containing varying ratios of nitrogen to oxygen, with the result that we have been able to make investigations over the temperature range 1400° to 2600° C., at an initial pressure of 1 atmosphere. At the lower temperatures dissociation must be negligible, and, on the assumption that combustion is complete at maximum pressure in mixtures containing a heavy excess of hydrogen, we were able to estimate the amount of the incomplete combustion in mixtures which do not contain an excess of hydrogen. Our results are shown in the following table:

Minimum Values for percentage Incomplete Combustion at Maximum Pressure.

Hydrogen (per cent.)	Ratio of Nitrogen to Oxygen.				
	0	2	3·7	4·8	5·8
15	6·6	..	..	..	..
16	8·0	7·0	.	..	3·0
18	9·0	8·3	..	..	3·0
20	9·0	9·0	4·5	6·8	3·5
22	..	10·0	6·0	8·0	5·6
24	..	10·8	7·3	8·0	..
26	..	..	7·7	..	..

We are now convinced, however, partly on account of the comparatively small variation in the calculated specific heats over such a wide range of temperature, and partly owing to the results of work by the aid of flame photography now being carried out in conjunction with Messrs. S. G. Richardson and W. Davies, that even with excess hydrogen present, combustion is far from being complete at the moment of maximum pressure. The values for incomplete combustion shown in the table are therefore much too small.

We have not yet published these results, because we wish to combine them with similar experiments at varying initial density. It is thought possible, in view of the fact that the ratio of the maximum pressure developed to the initial pressure for any given mixture strength increases as the initial pressure increases, that the apparent specific heat will, with increasing density, show an asymptotic approach to the true value.

Carbon Dioxide Tension in Tissues in Relation to Cancerous Cells.

In a paper which appeared in the *British Medical Journal* of Jan. 28 last, I brought together a number of facts from which the deduction was made that a localised increase of the carbon dioxide tension in the tissues, due to a diminished blood supply, may be an important factor in the cancerous change of cells, and may even be the factor common to many known 'causes' of cancer. Exactly how an increase in carbon dioxide tension could alter the cells so that afterwards they continue to behave in an abnormal manner for a vast number of generations, was not suggested. Some recent observations made upon *in vitro* cultures of rat kidney under varying carbon dioxide tensions are suggestive in this connexion. Before dealing with these, and in view of the fact that both X-rays and radium cause cancer, I propose very briefly to refer to some of the effects of these radiations on living cells.

The early workers exposed eggs and noted death or abnormal development according to the dose. The smaller the dose the less was the deviation from normal development. At the same time, it was noted that mitosis was very abnormal after radiation, the chromatin being especially effected. It was not, however, until recently that attempts were made to see whether there was any effect on inheritance. We now know that inheritance is altered. This information at once suggests an explanation for the cancerous change of cells after exposure to X-rays or radium. It may well be that during abnormal mitosis there is an abnormal distribution of genes or even chromosomes between the daughter cells, so that like produces not like, but unlike, and a normal cell becomes a cancer cell. Now, abnormal cell division not only follows radiation, but has also been observed under other abnormal conditions, and the observations referred to show that they occur when cells are incubated *in vitro* in high concentrations of carbon dioxide. Fig. 1 shows a number of metaphases of fibroblasts extruded from cultures of rat kidney. The numbers in the diagram give the pressure of carbon dioxide in mm. of mercury. It is seen that fragments of chromatin, chromidia, are not suspended at the equator of the spindle, but are situate in the neighbourhood of the centrosomes. They appear to be outside the spindle, and often surrounded by a small amount of clear cytoplasm or nucleoplasm. These appearances have not been seen in cultures grown in lower concentrations of carbon dioxide. They suggest that as a result there is an unequal division of chromatin between the daughter cells, with the possibility of accompanying hereditary disturbance. Thus a hypothesis with regard to cancer following radiation will apply also to cells subject to other adverse conditions.

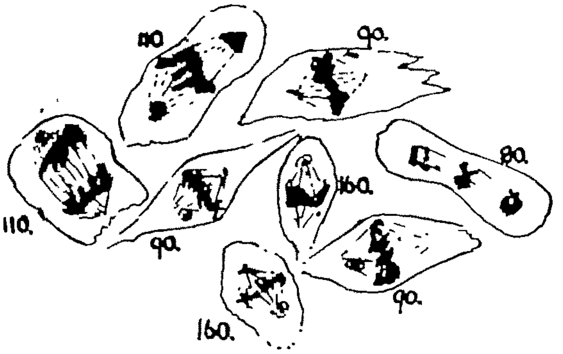

FIG. 1.—Metaphases of fibroblasts extruded from cultures of rat kidney. Cultures were fixed in Bouin's mixture and stained with Weigert's hæmatoxylin.

Correlation Coefficients in Meteorology.

IN the *Meteorological Magazine* for February, a much criticised statistical theorem of W. H. Dines is restated by F. J. W. Whipple. The original theorem was to the effect that "If there is a cause X and a result Y with a correlation r between them, then in the long run X is responsible for r^2 of the variation of Y." It is suggested that this be altered to "If the correlation coefficient for two variables X and Y is r, and if the appropriate regression equation is used for estimating X from known values of Y, then x', the estimated departure of X from the mean, is related to x, the true departure of X from the mean, by an equation of the type

$$x' = r^2x + \xi,$$

in which ξ is a variable quantity not correlated with x." A rider is added to the effect that the rule involves no assumption as to the distribution of the values of x and y, and no assumption as to the existence of other correlated variables.

That the subject of correlation is full of pitfalls for the unwary, is well illustrated by an example given of the practical use of the theorem in its revised form, added for the benefit of readers unfamiliar with the theory of correlation. In this example, which deals with two places, A and B, between the annual rainfalls of which there is a correlation coefficient of $\frac{1}{2}$, it is calculated that in years when A has an excess of 8 inches, the calculated excess at A obtained from B's rainfall would be $(\frac{1}{2})^2 \times 8$, that is, only 2 inches. But unless the relationship between two variables be linear, the regression equation gives no information about the average value of one variable that will be associated with one particular value of the other, and the example is therefore a misuse of both the original and the revised theorems. It is in any event difficult to see why a special theorem is necessary in order to emphasise the importance of the square of the correlation coefficient, unless it be to show that, having found a correlation of r between X and Y, it is still possible that a correlation, not of $1 - r$, but of $1 - r^2$, may exist between X and some third variable independent of Y.

To mention another important source of error in the use of the correlation coefficient, meteorological literature abounds in examples of a quite indefensible process whereby the existence of a genuine connexion between two quantities is made to appear far more probable than is actually the case. The process is a misuse of the equation

$$\sigma = \frac{1 - r^2}{\sqrt{N}},$$

which gives approximately the 'standard error' of r in terms of the true value of r (not yet known), and of N, the number of pairs of mutually 'independent' observations used in finding r', the apparent correlation coefficient. In order to see whether r' may not be fortuitous, that is, an error of sampling from uncorrelated material, the value 0 should clearly be used for r in the first instance in the above equation, yet the usual practice is to give it the value r': the reality of r' is assumed before this has been established. Let us suppose that r' be found to be 0·7 from 16 pairs of observations, then σ is calculated to be

$$\frac{1 - (0{\cdot}7)^2}{\sqrt{16}} = 0{\cdot}13$$

instead of

$$\frac{1 - (0)^2}{\sqrt{16}} = 0{\cdot}25.$$

Now 0·7 is not sufficiently large compared with 0·25 to be accepted with very great confidence, and the reality of the connexion would be doubtful. Had the true standard error of sampling been 0·13 on the other hand, the odds in favour of a genuine connexion would have been overwhelmingly great.

E. V. NEWNHAM.

The Buoyancy of Whales.

MANY questions arising in connexion with whales have yet to be answered satisfactorily; why, for example, do whales recently dead float in some cases, and in others sink?

Whales may be attacked with the hand-harpoon, weighing about 10 lb., with the simple gun-harpoon weighing about 12 lb., or with the Norwegian bomb-harpoon weighing about 150 lb.

Whales struck or harpooned with the hand harpoon or with the simple gun-harpoon rarely die at once but survive, and after descending to a great depth, return to the surface, when they are again attacked with harpoons, being finally despatched with whale-lances; a few, however, of those that survive and descend, fail to return to the surface and are drowned.

Greenland whales, bottlenoses, narwhals, and probably other species as well, irrespective of age, sex, or individual peculiarity, that die at the surface invariably float, while those dying at a depth invariably sink.

Greenland whales dying at the surface, notwithstanding the thickness of their blubber, float no higher than bottlenoses or narwhals; as Scoresby says, they barely float, while those dying under water exert a heavy downward strain on the whale-line, and if it breaks, or if the harpoon draws, the prize is lost.

How are the foregoing facts to be explained? It appears, from a consideration of all the circumstances, that whales usually retain sufficient air in their lungs to enable their bodies to float, but that if a whale dies by drowning and this air escapes, its body sinks, like that of any other mammal. Death by drowning is, however, a fate which only overtakes whales that have descended to a depth and are in some way or another prevented from returning to the surface. Whales that die at the surface do so not from drowning, but from exhaustion or shock, and as the blow-holes are valvular, the air required to give them bouyancy is retained and their bodies float, unless weighted by heavy harpoons and heavy whale-lines.

The instinct of the whale to descend when attacked, and the necessity it is under of returning to the surface to breathe, were fortunate circumstances for the old whalers, for the first exhausted it and the second made it easy to attack the whale a second time. The failure of a large whale struck with a light harpoon to reappear at the surface was an embarrassing circumstance for the old whalers, owing to the time wasted in raising it, and the risk of drawing the harpoon in the process. In 1876, in the Greenland Sea, a large Greenland whale struck with the gun-harpoon, descended to a depth of 900 fathoms and died in a little under an hour. To allow gases to generate and make the whale easier to raise, it was allowed to remain suspended by the line for ten hours; the actual raising of it occupying six hours. On another occasion, when a large hoary-headed old bottlenose was being raised, the harpoon drew when the prize was only 50 fathoms from the surface.

Harpooned whales that descend to a great depth seem to feel the weight of the whale-line when returning to the surface, and if the harpoon is wrongly placed, they feel it more than usual, and may fail to reach the surface and consequently drown; at least this is the explanation given in one case of which I know.

Nebulium and Hydrogen in New Stars.

In a recent paper (Nature, Jan. 28, p. 136) S. R. Pike pointed out that the condition of coexistence of O^{++} and H lines in the spectra of new stars leads to a density of the order 10^{-7} gm./c.c., which is directly opposed to the current ideas that forbidden transitions can occur only at very low densities, as determined, for example, by C. T. Elvey (Nature, Jan. 7, p. 12) using the 'expanding shell' theory of novæ. Since Mr. Pike's arguments are equally applicable to the spectra of planetaries, it seems of importance to analyse the subject further and to find the probable way out of the difficulty. I think that the real cause of the discrepancy mentioned is involved in the use of Saha's formula, which holds only in thermodynamic equilibrium, and of course cannot be applied to the gaseous shells as produced by the expansion of novæ or those of planetary nebulæ, because in these cases the exciting radiation is extremely diluted; a more general ionisation formula is to be used.

Let us suppose with Mr. Pike that 'coexistence' means that not more than 99·9 per cent. of H is ionised and not less than 0·1 per cent. of O$^+$. The lowest temperature at which those two substances (H and O$^+$), having ionisation potentials χ_1 and χ_2 at the same electron pressure, can coexist by the ordinary Saha's formula as used by Mr. Pike, is $T = 840\ (\chi_2 - \chi_1)$. In our case ($\chi_2 = 29{\cdot}5$; $\chi_1 = 13{\cdot}5$) and the *minimum* temperature required will be $T = 13{,}000°$, and the density (for H) only 10^{-8} gm./c.c. in decisive contradiction to all our present ideas on the nebulium spectrum. But let us take a more correct formula for ionisation by diluted black body radiation (temperature T), when the electron temperature is T_e and the dilution factor is W. For small optical thickness of the gaseous shell we have

$$\frac{X_{i+1}}{X_i}N_e = We^{-\chi/\kappa T}(2\pi m)^{\frac{3}{2}}(\kappa T_e)^{\frac{1}{2}}\kappa T/h^3$$

where N_e is the number of electrons per c.c. (*Proc. Am. Acad.*, 62, 5; 1927; Harvard Reprint 38). The dilution factor, W, can be easily estimated for Nova Aquilæ 3, using Hubble and Duncan's data, as previously used by Elvey. Taking the rate of expansion of the shell as 1700 km./sec. during 19 days, we find that for the first appearance of the nebulium spectrum the distance of the shell d from the original star was $2{\cdot}8 \times 10^9$ km. We can reasonably suppose that the nuclear star has a radius R of the order of one solar radius, that is, of 7×10^5 km.; we obtain, therefore, $W = \left(\frac{R}{d}\right)^2 = 6 \times 10^{-8}$. Now neglecting the unknown difference between T and T_e, we calculate that the resulting density of the shell is 6×10^{-16} gm./c.c. By his method Elvey obtained 2×10^{-17}; taking into account the very rough character of our calculations, we can consider the agreement as very satisfactory and the difficulty raised by Mr. Pike as settled.

It is noteworthy that the calculated density of an expanding gaseous nova envelope (planetary nebula *in statu formandi*) appears to be from 10^2 to 10^3 times higher than that of an already formed planetary, as determined by the theory of a gaseous shell supported by radiation pressure (*Astr. Nach.*, 225, 90; 1925).

The Polarisation Factor in X-ray Reflection.

In comparing the observed intensity of X-ray reflection from crystals with the theoretical formulæ, and in particular in calculating the atomic scattering factor, F, from measurements of the absolute intensity of reflection, it has always been assumed that the incident X-ray beam is unpolarised. This has the effect of introducing a polarisation factor $\frac{1}{2}(1 + \cos^2 2\theta)$, where θ is the glancing angle of reflection, into the expression for the intensity of reflection. Now experiments by Bishop (*Phys. Rev.*, 28, 625; 1926) show that the characteristic radiation from a molybdenum Coolidge tube may be 15 per cent. polarised, and Kirkpatrick (*Phys. Rev.*, **29**, 632; 1927) points out that this must have introduced errors into the values of F calculated from experiment. He calculates for the polarisation factor

$$\{\sin^2 \alpha + P\cos^2 \alpha + (P\sin^2 \alpha + \cos^2 \alpha)\cos^2 2\theta\}/(1+P),$$

where P is a measure of the degree of polarisation of the incident beam, being unity for an unpolarised beam, and α is the angle between the plane of reflection and the plane containing the incident beam and the electron stream in the X-ray tube.

In most experiments α has been zero and, in this case, a degree of polarisation such as that indicated by Bishop would introduce errors of perhaps 5 or 10 per cent. into the values of F determined experimentally for large angles of scattering. This has been pointed out by Havighurst in a recent paper (*Phys. Rev.*, **31**, 16; 1928).

Now Kirkpatrick suggests that it would be advisable in all such experiments to work with $\alpha = 45°$, since in this case the polarisation factor reduces to $\frac{1}{2}(1+\cos^2 2\theta)$, and is independent of the degree of polarisation of the incident beam.

In view of the detailed comparison of the theory of atomic scattering with experiment which has been based on them, it is perhaps worth while to state that in the determinations of F recently published by the writer and Miss Firth (*Proc. Roy. Soc.* A, **117**, 62; 1927), α was in fact 45°, so that these results would appear to be unaffected by this source of error. It is, however, only fair to state that this value of α was used for reasons of practical convenience and not because of any particular foresight on our part.

Spectrum of Ionised Sodium.

FOLLOWING the extension of the irregular doublet law given by Messrs. Saha and Kichlu [NATURE, Feb. 18, p. 244], I have tried to analyse the spectrum of Na^+, proceeding from the spectrum of neon. I have been able to identify the lines $5L_2(M_1 \rightarrow M_2)$ completely, and the lines $5L_2(M_2 \rightarrow M_3)$ partially. The combination $5L_2M_1$ gives four terms ${}^3P_{0\,1\,2}$, ${}^1P$ analogous to Paschen's s_2, s_3, s_4, s_5 of neon. The differences ${}^3P_0 - {}^3P_1 - {}^3P_2$ are -765 and -592 and ${}^3P_1 - {}^1P_1 = 3072$. The combination $5L_2M_2$ gives 10-terms $\begin{pmatrix} {}^3D & {}^3P & {}^3S \\ {}^1D & {}^1P & {}^1S \end{pmatrix}$ analogous to Paschen's p-terms. They have been all identified with the exception of ${}^1S_0$, and the differences are found to be roughly double the corresponding neon differences (Paschen's P-terms).

There seems to be strong reason for supposing that the identification is quite precise; for Millikan and Bowen (*Phys. Rev.* vol. 23) discovered two lines in the hot-spark spectrum of Na having the wavelengths λ372·3 and λ376·6 with the frequency difference 3075. They are just the fundamental lines ${}^1S_0 - {}^3P_1$ and ${}^1S_0 - {}^1P_1$ arising from the transition $6L_2 \rightarrow 5L_2M_1$. 3072 is just the difference found for $({}^3P_1 - {}^1P_1)$ in my analysis.

Assuming that the value of $5L_2M_2$-terms $= 4N/3^2$, the value of the ionisation potential of Na^+ comes out to be about 47 volts, with a radiation potential at 32·8 volts. Mohler's values obtained from the electron bombardment methods are respectively 45 volts and 35 ± 1·5 volts. Considering the limitations of this method, the agreement seems to be quite tolerable.

The full analysis will be published shortly.

Mnemotropism: Persistence Tendency in Remembering.

MANY hundreds of estimates of given short time intervals incidentally revealed a tendency of successive estimates to approximate each other. For example, in a thousand estimates of ten seconds, varying from 8 to 16·2 seconds, the frequency of differences between successive estimates can be summarised as follows:

0-2 seconds	556 times
-4 ,,	288 ,,
-6 ,,	110 ,,
6 + ,,	45 ,,

There appears to be a tendency to repeat compensatory under- or over-estimates, for example, 10, 6, 10, 7, 10, 7 seconds; or, 11, 8, 6, 12, 8, 6, 12, 8, 8, 7, 11, 7 seconds.

This mnemotropism is comparable to the tendency recently described by Prof. Cathcart and Dr. Dawson (*Brit. Jour. of Psychology*, Jan. 1928) as 'diabatic' or 'persistence.' Working on an ergometer, they found that the rate at which repetitive movements are reproduced is deflected towards the rate at which intervening movements of a similar kind have been made. They also point out that 'persistence' shows itself in piano playing.

The circumstance that estimates of given time intervals appear to run in series (of either low, approximately correct, or high figures), further demonstrates the existence of a momentum or persistence in remembering. It may be added that, in my own crude stop-watch experiments, the interval of ten seconds (that is, 10·0*s*) was estimated correctly in only 2 per cent. of the tests, and in 2·7 per cent. only of one thousand estimates of twenty seconds (20·0*s*).

The Urinogenital Organs of the Male Frog (*Rana temporaria*).

AN interesting error occurs in the description of the male urinogenital organs of the male frog (*Rana temporaria*) in such standard works as Ecker's "Anatomy of the Frog" (Haslam's translation), Wiedersheim and Parker's "Comparative Anatomy of Vertebrates," and Parker and Parker's "Practical Zoology." Briefly, it is stated that sperms pass through the vasa efferentia to enter a longitudinal duct in the kidney, and thence through transverse ducts in the kidney to the ureter, which acts as a vas deferens.

I have consulted a number of more recent textbooks, *e.g.* those of Borradaile, Bourne, O'Donoghue, Thomson, etc., and find that they state that the vasa efferentia open to the kidney and that the sperms pass through the *kidney* tubules to the ureter; no mention being made either of the longitudinal or transverse ducts of the older writers.

This latter statement coincides with my own observations on a very large number of sections. Not only have I failed to discover any trace of special seminiferous tubules in the kidney, but I have on several occasions examined sections in which sperms were clearly to be seen in very large numbers in the ordinary urinary tubules.

I have, however, failed to find any contradiction of the statement of Ecker and his contemporaries; the two diverse statements being equally available to zoology students.

Action of Lead-tetra-ethyl in Delaying Detonation in the Internal Combustion Engine.

By Dr. E. Mardles.

The arrival in Great Britain from the United States of ethyl petrol—the anti-knock fuel containing 6 c.c. of ethyl fluid (lead-tetra-ethyl 54·5 per cent.; ethylene dibromide 36·5 per cent.; and monochlornaphthalene 9 per cent., with a trace of Sudan IV. Red dye) per gallon of petrol, has aroused public interest in the remarkable action of minute quantities of lead-tetra-ethyl and other substances in delaying detonation or 'knocking' in the internal combustion engine. Questions have been raised in the daily press with regard to the benefits to be derived from the use of 'doped' fuel, and as to whether its use is attended with any ill effects on the health or any deleterious action on the mechanism of the engine.

In brief, distinct advantages are to be gained by the use of 'anti-knock' fuels; deleterious action on the engine mechanism by the use of ethyl petrol, if any, is negligible, whilst after investigations in the United States no grave poison hazard appears to have been discovered. The petrol has been sold in America since 1923, and although about 800 million gallons U.S. have been consumed, no illness attributable to its use has been found. In Germany iron-penta-carbonyl in petrol is marketed under the name Motalin as an anti-knock fuel.

Action of Lead-tetra-ethyl.

The main function of the lead-tetra-ethyl is to mitigate the distressing engine trouble of 'knocking' or detonation which arises when a car is accelerating or climbing with open throttle on top gear, especially when the cylinders contain carbon deposits or when an inferior fuel is used. The halogen compounds, namely, ethylene dibromide and monochlornaphthalene, help to remove the lead from the cylinder in the form of lead halogen compounds after the lead-tetra-ethyl has done its work, and they also contribute slightly to the anti-knock action.

It has been found impossible to use an ordinary straight run petrol for high compression engines such as are used for aeronautical or racing purposes without loss of power due to detonation, and it is necessary to employ either mixtures of petrol with benzene, alcohol, etc., for these purposes or to add a small amount of an anti-knocker, such as lead-tetra-ethyl. Ethyl petrol with increased amounts of 'dope' was employed in the winning of the Schneider Trophy (1927) and by Capt. M. Campbell in establishing the world's record of motor-car speed, February 1928.

Engine Experiments with Ethyl Petrol.

For ordinary purposes the following engine experiments illustrate the typical action of 5 c.c. ethyl fluid per gallon of petrol. In a comparatively low performance water-cooled engine which detonated badly at 5 to 1 compression ratio when run on petrol alone, detonation was immediately suppressed when run on the ethyl mixture, and the compression could be raised to 6 : 1 before detonation began. It was calculated from the data obtained that an increase in power of 10·5 per cent. and a decrease in consumption of fuel of 6 per cent. were obtained by employing the higher compression.

In a high performance air-cooled engine at 5 : 1 compression ratio, a slight gain in power was always noticed on changing over from petrol to the ethyl mixture without altering any other condition. Detonation as before was suppressed, and a further gain in power could be got by increasing the magneto advance.

Compression and Efficiency.

The development of the internal combustion engine has been seriously impeded by the tendency of an ordinary straight run petrol to detonate when the compression ratio is raised above 5. It will be seen from Table I., prepared from tests carried out by Ricardo, that considerable progress can be made with the use of higher compression ratios involving an annual saving in the aggregate of many million pounds sterling.

Table I.

Compression Ratio	Indicated Horse-power.	Indicated Thermal Efficiency.
4	30·3	28·8
5	33·1	32·8
6	35·2	35·9
7	36·8	38·3

Highest Useful Compression Ratio.

H. Ricardo discovered (1918) that though detonation in the internal combustion engine is influenced by a number of important factors, for example, magneto timing and position of plugs, mixture strength, design of piston head, and cylinder shape, etc., the trouble is due to a specific failing of the fuel. Under standard conditions, using a variable compression engine, the E.35 type, he

Table II.

Highest Useful Compression Ratios of Substances (Ricardo).

Substance.	H.U.C.R.
Aromatic free petrol	4·85
Kerosene (heavy fuel)	4·2
Cracked spirit (53 per cent. unsaturated)	5·55
Pentane	5·85
Hexane	5·1
Heptane (normal)	3·75
Carbon disulphide	5·15 (pre-ignition at this point)
Benzene	6·9 (ditto)
Toluene and Xylene	7·0
Cyclohexane (93 per cent. pure)	5·9
Ethyl alcohol (98 per cent.)	7·5
Methyl alcohol	5·2 (pre-ignition at this point)
Butyl alcohol	7·3
Ethyl ether	3·9

determined the point at which during increasing compression the engine gave the first audible signs of detonation. This point he has referred to as the Highest Useful Compression Ratio (H.U.C.R.), that is, the highest compression ratio which it is worth while to employ with a given fuel. If the compression ratio is raised above this limit, excessive detonation leads to pre-ignition and loss of power.

The anti-detonating action of lead-tetra-ethyl is seen at a glance from Table III., which has been compiled from engine data obtained at the Air Ministry Laboratory, Imperial College of Science and Technology, and shows the effect on the H.U.C.R. of a fuel by the additions in varying amounts.

TABLE III.

	Brake Mean Effective Pressure.	H.U.C. Ratio.
Petrol	122 lb./sq. in.	4·9
Petrol + 0·05 per cent. lead-tetra-ethyl .	126 ,,	5·3
+ 0·1 ,, ,, .	131 ,,	5·7
+ 0·2 ,, ,, .	138·5 ,,	6·5
+ 0·3 ,, ,, .	142 ,,	7·0
+ 0·4 ,, ,, .	144 ,,	7·35

The petroleum refiner, in an endeavour to increase the yield of petrol fraction by including a part of the less volatile distillate which was formerly put into the kerosene fraction, produces a motor fuel which has a greater tendency to 'knock,' but by the use of anti-knockers this disadvantage is removed.

CONDITION OF ENGINE PARTS AND DEPOSITS.

The results of prolonged engine trials with fuel containing not more than 6 c.c./gal. confirm the claims made that ethyl petrol will not injure spark plugs, valves, or stems. After a 33-hour continuous run, an engine which was stripped showed a slight grey oily deposit slightly different from the usual appearance.

Typical analyses of the deposits are as follows:

TABLE IV.

I. Total weight of deposit from piston head and exhaust valve . 2·3 gm./40 sq. cm.
Total weight of lead present in the petrol . . . . . 28·5 gm.

Deposit analysis.	Per cent.
Oil	4·4
Lead bromide and sulphate . . .	12·2
Iron and aluminium bromides . . .	0·2
Carbon and volatile matter . . .	77·1
Oxides of iron and aluminium . . .	5·4

Lead was found to be present in the oil, but not bromine.

TABLE V.

II. Total weight of lead added . . . 83·7 gm.

Analysis of deposits.	Total weight, grams.	Lead per cent.	Total weight of lead, grams.
Engine head samples:			
Grey deposit . .	38·23	54·09	20·7
Black deposit . .	13·49	21·04	2·8
Exhaust pipe:			
First 2 ft. section .	106·14	27·80	29·5
Remainder . .	12·79	2·26	2·9

Total lead in crank case (oil and deposit) . . 10·5
Total lead in drop pans under exhaust outlet . . 1·0
Total lead from all deposits . . . . 67·4

The amount of lead in the exhaust gases (undiluted and containing 7 per cent. carbon monoxide) was on an average 150 mgm. per 10 cub. metres.

EXPLANATIONS OF THE PHENOMENON OF DETONATION.

Ricardo from his engine experiments (1918) concluded that detonation differed entirely from pre-ignition, and attributed it to the spontaneous inflammation of residual unburnt charge owing to its compression by the expanding burnt and burning portion. The ignition of the residual charge under high compression and at high temperatures would cause a rapid rise in pressure, causing the cylinder walls to vibrate as though struck by a hammer.

Tizard and Pye extended Ricardo's line of investigation, and studied in particular the behaviour of gaseous mixtures under adiabatic compression. They found that carbon disulphide gave much greater lag periods, subsequent to the arrest of the piston before the rise in pressure due to inflammation occurred, than did ether or heptane, both of which detonate at low compressions, whilst carbon disulphide tends to raise the H.U.C.R. when added to a fuel. They concluded that detonation is a function of the temperature coefficient of the reaction velocity of combustion of a fuel, the lag period being an indication of this value.

Midgley and Boyd (1922), who first discovered the anti-detonating properties of lead-tetra-ethyl and other organo-metallic compounds, aniline, etc., in the engine, considered that detonation is set up in the cylinder when the rate of advance of the flame front reaches the velocity of sound. They attribute such a high rate of flame propagation to a high reaction velocity of combustion. The addition of substances which raise or lower this reaction velocity correspondingly should promote or delay detonation. They showed that isoamyl nitrite promotes detonation to a remarkably high extent, whilst other substances lower it to a greater or less extent, as shown by their results in Table VI.

TABLE VI.

Substance.	Volume in petrol required to effect a given suppression in detonation.
Benzene	25·0
Ethyl iodine	1·6
m. Xylidine	2·0
Tin-tetra-ethyl . . .	1·2
Selenium ethyl . . .	0·4
Tellurium ethyl . . .	0·1
Lead-tetra-ethyl . . .	0·04

Midgley and Boyd employed a ¾-kw. Delco-light engine and measured the degree of detonation by means of a rod or pin resting freely on a steel diaphragm set in the cylinder head. When detonation occurred the pin was bounced free from the cylinder, and by means of an electrolytic cell the time whilst in the air was measured from the volume of gas collected. This method is used in the United States, whilst the variable compression engine is employed in Great Britain for measuring the detonation tendency of a fuel.

The view that detonation in the engine is the same phenomenon of rapid wave propagation observed by Berthelot and Le Chatelier with gaseous explosions in long tubes is now considered to be incorrect, since the engine cylinder is too short to render this probable, and an analysis of the pressure diagrams of Tizard, Pye, and Dixon shows that there is no abrupt transition to the detonation wave during sudden compression. Egerton and Gates found that 'anti-knocks' did not affect the position of detonation in a tube 150 cm. long, even up to initial temperature of 230° C. and pressures of about 100 lb./sq. in.

Nuclear Drop Theory of Callendar.

A theory proposed by Prof. H. L. Callendar (1925) explains in a lucid and simple manner the phenomenon of detonation, and throws light on a large number of isolated facts left unexplained by numerous other theories. In brief, it regards detonation to be due to the simultaneous and violent ignition of a comparatively large volume of unburnt charge containing droplets or nuclei. When petrol is atomised in a current of air, the drops as they evaporate leave a residue or nucleus consisting chiefly of the less volatile constituents, such as the heavier paraffins, which have low self-igniting temperatures and serve as foci of ignition. When benzene and pentane and other fuel vapours are *compressed* they show cloudy condensation. Again, when gaseous mixtures, such as acetylene in air, are heated, a thick fog of ionised particles is produced which sensitises the mixture to ignition. It can be demonstrated that the self-ignition of a gaseous mixture containing liquid droplets is sometimes more than 100° C. below that of the mixture entirely in the vapour state. The inflammation, too, is far more violent in the presence of drops. Thus, a fine spray of amyl nitrite ignited with a violent explosion when projected into a glass tube at 140° C., but the vapour–air mixtures caught fire relatively mildly when a temperature of 480° was reached.

The subject of the formation of ionised particles or nuclei in gaseous media and the chemical changes which occur during the slow combustion in the pre-flame period during adiabatic compression is of considerable significance to the subject of detonation, and is being studied at the Air Ministry Laboratory of the Imperial College of Science and Technology. Quantitative analysis of the products of slow combustion of various fuels shows that aldehydes and acids are formed in profusion, but since these do not promote detonation in the engine, a prior compound was suspected. Further investigations indicated the presence of active oxygen, presumably in the form of organic peroxides, in the condensation products, especially when liquid drops were present and the mixture heated for a few seconds only. It was considered that the aldehydes, carbon monoxide, etc., were the decomposition products of primarily formed peroxides of the fuel, which by concentration in the nuclear drops caused self-ignition of an exceedingly violent character at relatively low temperatures. Organic peroxides are known to be violent explosives. Thus Brodie, who first prepared alkyl peroxides, showed that a few drops detonated like a cannon. Staudinger also found that small quantities of organic peroxides adhering to the walls of a beaker were sufficient to shatter it.

Engine Experiments with Organic Peroxides.

In engine experiments carried out with the use of a synchronised sampling valve, portions of the gas mixture during the compression stroke and before ignition have been withdrawn for analysis. The oxidation products were found to contain aldehydes, acids, etc., and to be similar to those obtained during slow combustion experiments in glass tubes or bulbs in the laboratory. In a 4-stroke engine running at 1200 r.p.m.—that is, with a compression stroke of $\frac{1}{40}$ of a second duration—the presence of active oxygen was demonstrated. With the addition of iron carbonyl or lead-tetra-ethyl to the fuel, the yield of peroxides was appreciably diminished. Experiments were tried with the use of petrol to which small additions of organic peroxides and nitrogen peroxide had been added, and it was found that they all promoted detonation to a marked degree.

Moureu, Dufraisse, and Chaux, working on the autoxidation of hydrocarbons, confirm Callendar's conclusion that peroxidation occurs in the liquid state and is responsible for detonation. Callendar from his experiments (1925) showed that lead particles from the thermal decomposition of lead-tetra-ethyl became concentrated on the surface of nuclear drops, which are in this manner protected against rapid oxidation and early self-ignition, the primary higher oxides formed by the oxygen molecule with the fuel being immediately decomposed by the metal and autoxidation thus delayed.

Experiments with Metallic Vapours.

Egerton and Gates demonstrated that lead vapour from a low tension arc behaved similarly to lead-tetra-ethyl in raising the self-igniting temperature of fuel mixtures and delaying detonation in the internal combustion engine. They investigated the action of anti-knockers and metallic vapours on the self-igniting temperature, determined by the Moore method, of petrol mixtures, and found, for example, that with thallium vapour a rise of 180°, and with lead a rise of 100°, was obtained. Lead-ethyl gave a rise of 90°, iron carbonyl 130°, and selenium diethyl 140°. They concluded that the stable peroxides of the metal react with and destroy the fuel peroxides, for example, aldehyde peroxide, and are then regenerated so that in this way the substances which autocatalyse combustion are destroyed.

Ionisation and Radiant Energy.

Detonation in the engine is accompanied by marked ionisation, and the spectrum of 'knocking' combustion shows an extension in the ultra-violet region. It was considered (Symposium on Gaseous Reactions, Faraday Society, 1926) that these phenomena are the accompaniment rather than the cause of detonation, though at one time it was considered that 'anti-knocks' acted by absorbing either the radiant energy or the electrons which by advance from the flame front increased the flame propagation and so led to detonation.

Bennett (1927), who studied the influence of substances on the ionisation of various flames and on ionisation during the slow combustion of a number of gas mixtures, found *inter alia* that lead-tetra-ethyl, and iron carbonyl, as well as amyl nitrite, greatly increased the ionisation. It was considered, therefore, that ionisation was not a cause of detonation but merely a temperature effect.

Landlocked Salmon.

FOR many years there has existed in the middle and upper parts of the River Otra, in southern Norway, a fish known locally as the 'Blege,' a name applied throughout the whole of south-western Norway chiefly to the juvenile stages of the sea trout. In fact an important fishery for the 'Blege' took place in old days in the southern parts of the Bygglandsfiord, a fishery mainly restricted to the spawning season late in the autumn and lasting until Christmas.

It is only recently [1] that this fish has been discovered by Mr. Knut Dahl to be a true landlocked salmon (*Salmo salar*). Only exceptionally does this salmon exceed 30 cm. (about 12 in.) in length, and for this reason Mr. Dahl has called it a 'Dwarf-salmon.' In general appearance it resembles an overgrown smolt, through the silvery coat of which the blue parr- or finger-marks are still faintly visible. An examination of such characters as the number of scales in the oblique row running backwards from the adipose fin to the lateral line, the shape and slenderness of the tail, and the short upper jaw, shows that it is indistinguishable from the young of typical migratory salmon, its only difference from the adult salmon being the retention of certain characters peculiar to the juvenile stages and its small size.

The adult fish are somewhat pelagic in their habits and roam about in schools all over the lake, unlike the ordinary trout, which appear to keep more to the shallow water and do not congregate so markedly in shoals. This roaming character is probably correlated with their feeding habits, since their food chiefly consists of the planktonic crustacean, *Bosmina obtusirostris*. Scale examination shows that many exhibit the typical growth periods of the migratory salmon, spending their first years in the river under poor feeding conditions, and then migrating into the lake where food is more abundant. Some, however, are born in the lake itself, and do not show this change in growth rate. A migratory habit is also exhibited by the landlocked salmon of Lake Wenern, which migrate into the river to spawn, returning afterwards to the lake, but unlike the dwarf-salmon they grow to a considerable size. Of the dwarf-salmon born under river conditions, the majority migrate after 2-5 winters. Most of the fish captured were of an age of four to six winters, and older fish were rare. Spawning took place for the first time generally in the fifth or sixth winter.

True salmon are prevented from migrating into these waters by high falls situated at Vigelandsfoss, 15 kilometres from the sea, and from geological evidence Mr. Dahl estimates that the dwarf-salmon must have arisen from fish landlocked about 9000 years ago.

At the present day the impression gained was that these fish were as numerous as the common trout, though the net fishing has diminished owing to the damming of the Bygglandsfiord as a reservoir. Mr. Dahl gives a vivid description of the sport afforded by the dwarf-salmon to the angler, and maintains that in fighting powers they surpass the trout; a supremacy which they hold also as a table delicacy.

F. S. R.

[1] The "Blege" or Dwarf-salmon. A landlocked salmon from Lake Bygglandsfiord in Setesdal. By Knut Dahl. *Skrifter utgitt av Det Norske Videnskaps-Akademi i Oslo.* I. Matem.-Naturv. Klasse 1927. No. 9. Oslo, 1927.

Research and Development in Australia.

THE main objects of the Science and Industry Research Act (1926) of the Commonwealth Government were to reorganise the Institute of Science and Industry, which was founded in 1920, and to provide adequate funds for developing scientific and industrial research in Australia. The first Annual Report of the Council for Scientific and Industrial Research (Melbourne, 1927) contains a review of the activities of this newly constituted body between April 1926 and June 1927; the Science and Industry Research Act, 1920–26, is printed as an appendix to the Report. At the first meeting of the Council, it was decided to devote particular attention to investigations on plant and animal pests and diseases, fuel problems, preservation of foodstuffs, and forest products. In accordance with this decision, arrangements were made to secure information and reports on some of the problems concerned from Prof. T. G. B. Osborn (Adelaide), Prof. H. A. Woodruff (Melbourne), Dr. Franklin Kidd (Low Temperature Research Station, Cambridge), Mr. A. J. Gibson (Indian Forest Service), and other specialists. The various fields thus laid open to inquiry are all of first-rate importance, but a particular interest may perhaps be anticipated for Mr. Gibson's report, which is to deal with forest products problems and with the advisability of establishing a forest products laboratory in Australia.

The Annual Report affords a comprehensive summary of the many investigations in progress, some of which have already been noticed in the Council's journal (see NATURE, Oct. 8, 1927, p. 520). Many of the activities of the Council have an intimate bearing upon the progress of agriculture in Australia. A standing committee on agriculture has been appointed; a register of agricultural research is being compiled; and the Council is drawing up plans, in collaboration with the British Empire Marketing Board, for the creation and organisation of a tropical agricultural research institute in Queensland.

In co-operation with the Development and Migration Commission and the Anglo-Australasian Tobacco Company, the Council is organising a comprehensive investigation of tobacco-growing in Australia, a sum of £30,000 having been made available for this purpose during the first period of three years. The citricultural research station at Griffith, in the Murrumbidgee irrigation area, is now owned and financed jointly by the Council and the Water Conservation and Irrigation Commission of New South Wales, the Commission contributing £1500 per annum and supplying water free of cost. For work in viticulture the Council has acquired the research station at Merbein, near Mildura; considerable success has attended the researches into manurial and processing problems which are in progress at this institute, the introduction of the 'cold-dip' process for drying sultanas having led to a gain in quality equivalent to some £30,000 during the last season. For reasons connected largely with the quality of the soil, it is proposed to establish a research station at Coomealla, 12 miles from Mildura, for the investigation of irrigation problems.

With regard to plant and animal pests and diseases, a report upon the practicability of controlling and eradicating St. John's wort by the introduction into Australia of suitable insect enemies has been furnished by Dr. R. J. Tillyard, and investigations are being conducted in England with *Chrysomela hyperici* and other species. Dr. B. T. Dickson, formerly professor of plant physiology in McGill University, has been appointed to direct a comprehensive series of researches dealing with the rusts and smuts of cereals, soil-infecting fungi, and plant diseases in general. Prominent among the animal pests under consideration is the cattle-tick; this has caused enormous financial loss in Queensland, and has only been kept out of New South Wales by the maintenance of a buffer area. It is now feared that the buffalo-fly, if permitted to spread southwards from the Northern Territory, may become a worse pest than the cattle-tick. In attempts to effect control by natural enemies, experiments are in progress with *Hydrotæa dentipes*, which may possibly parasitise the larvæ of the buffalo-fly, since in the larval stage it lives on the larvæ of the stable-fly and the house-fly.

News and Views.

Hearty congratulations are offered to the veteran engineer, Sir Alexander B. W. Kennedy, F.R.S., who celebrates his eighty-first birthday on Mar. 17. Born at Stepney, son of the Rev. John Kennedy, D.D., resident there, he was educated at the City of London School, entering, on the completion of school life, at the Royal School of Mines, South Kensington. His active technical career started with the firm of J. and W. Dudgeon, engineers and shipbuilders, Millwall, afterwards becoming chief draughtsman in Palmer's Engine Works, Jarrow. Elected professor of engineering at University College, London, in 1874, Sir Alexander, for fifteen years ensuing, devoted himself to the establishment of an engineering laboratory in which teaching and practice could proceed with harmonious interaction. Undoubtedly his work in this field had far-reaching results elsewhere. He designed the steel and concrete internal structure of the Alhambra Theatre, when for the first time, we believe, flat concrete slabs were used on a large scale to carry weights. Sir Alexander's services were utilised for many of the early electric undertakings in London and the chief provincial towns, and he was much in request as an official adviser on Government projects. He was president of the Institution of Mechanical Engineers in 1894–1895, and of the Institution of Civil Engineers in 1906–7. In an inaugural address entitled 'Engineering and Modern Life,' Sir Alexander said in modest vein, "I have worked in many branches, from marine to academic, from constructional to electrical. Having spent forty years in so many different wildernesses I cannot reasonably claim to know the ways of any one of them as thoroughly as my more judicious predecessors have shown in their particular regions." So long ago as 1894, at the Oxford meeting of the British Association, Sir Alexander was president of Section G (Mechanical Science).

Sir James Edward Smith, F.R.S., founder of the Linnean Society of London, and its president for forty years, died at Norwich, his birthplace, on Mar. 17, 1828. This centenary, relating to a distinguished botanist and leader of science, merits notice. Besides the foregoing, however, Sir James is remembered through his acquisition in early youth of the scientific collections, library, and manuscripts brought together by Linnæus, the great Swedish naturalist. Smith was the author of numerous botanical treatises; whilst his "English Botany" (1790–1814), issued in thirty-six volumes, with coloured figures by James Sowerby, achieved high success. He published a paper in the *Philosophical Transactions* in 1788, entitled "Observations on the Irritability of Vegetables." "Having heard," he begins, "that the stamina of the Barberry, *Berberis communis*, were endued with a considerable degree of irritability, I made the experiment in Chelsea Garden, May 25, 1786, on a bush then in full flower." It may be mentioned that in the same volume were papers by his eminent contemporaries, John Hunter, Priestley, and Cavallo. The Linnean Society possesses a portrait of Sir James. He was elected into the Royal Society in 1785.

The story of the purchase and transference of the Linnæus collections to England, to become the personal property of an individual barely twenty-five years old, is of singular import. The more or less accidental circumstance of breakfasting with Sir Joseph Banks on a certain morning in December 1783 was the mainspring. Smith had just completed his medical studies at Edinburgh, and was deeply interested in botany. He learnt from Sir Joseph that an offer had been made to him by Prof. Acrel, of Upsala, to acquire by purchase the whole of the collections made by Linnæus, with some later additions. The sum named was 1000 guineas. Banks for some reason or other had himself decided against the proposal; but he impressed the matter upon Smith. Correspondence with Prof. Acrel ensued; ultimately, with the provision of funds by Smith's father, the son, Dr. J. E. Smith, undertook to buy. The collections were to be entrusted to a master mariner sailing between Stockholm and London. On Aug. 13, 1784, the safe receipt of the collections in Stockholm was notified, and by the end of October following, the ship, *The Appearance*, Capt. Sweder, had arrived in the Thames with the precious packages.

THE sale of the collections incurred the grave displeasure of the King of Sweden, Gustavus III., who sent a vessel to intercept the voyage, and a courier by land to assist. These efforts, however, were unavailing. Apartments were taken in Paradise Row, Chelsea, for the accommodation of the collections, and soon Banks and Jonas Drylander were assisting in their arrangement. In March 1788, Dr. Smith removed to Great Marlborough Street, of course taking the series with him. After a six years' residence there he moved to Hammersmith, and finally to Norwich. He was knighted in 1814. Annually for forty years the Linnean Society had re-elected its founder as president. However signal the honour, reciprocity was not seen in the bequest of the collections to the Society. On the contrary, the council received an offer from Smith's executor to purchase the collections (as they then were, for some minor sales had occurred) for the sum of £5000. Ultimately 3000 guineas was accepted as the purchase price. But this financial responsibility held the Society to ransom for many years.

DURING the recent visit to Great Britain of Mr. W. Nowell, the director, considerable progress was made with the recruitment of the staff for the Amani Research Institute, or, as it is to be known, the East African Agricultural Research Institute, Tanganyika Territory. When Mr. Nowell was appointed, he had just taken up his duties as Director of the Department of Science and Agriculture, British Guiana, to which post he had been transferred from that of Assistant Director, Department of Agriculture, Trinidad. He lost no time, however, in visiting his new headquarters, and for a considerable period afterwards he toured extensively in East Africa to familiarise himself with local conditions and to become acquainted with the heads and staffs of the agricultural departments. During his visit to England last winter he was busily engaged in framing the general policy of the Institute and making arrangements for the recruitment of staff. Up to date, the following appointments have been made: entomologist, Mr. C. B. Williams, late Director, Plant Protection Service, Egypt; plant pathologist, Dr. H. H. Storey, late mycologist in charge of the Natal Herbarium, Union of South Africa; soil chemist, Mr. G. Milne, late lecturer in agricultural chemistry, University of Leeds; geneticist, Mr. G. F. Clay, late agricultural officer, Uganda; plant physiologist, Mr. F. J. Nutman, late of the Forest Products Research Laboratory; systematic botanist, Mr. P. J. Greenway, late of the Imperial Forestry Institute, University of Oxford. Mr. F. M. Rogers, who for the past few years has been in charge of the station pending its reorganisation, has been appointed superintendent of plantations, and Mr. K. E. Toms, lately of the Department of Agriculture, Zanzibar, assistant superintendent of plantations. Capt. E. M. Nicholl has been appointed manager of the Kivumkoro Coffee Estate which is now attached to the Institute. Mr. R. E. Moreau is appointed secretary and librarian.

THE capital expenditure on the East African Agricultural Research Institute, which must now be regarded as one of the chain of research stations which it is intended to establish throughout the tropical Colonies of Great Britain, is estimated at a total of £22,500. Towards this the Colonial Research Committee has provided £2000, whilst it is expected that the balance will be found from the East African Guaranteed Loan. The recurrent expenditure will be met partly by the East African Governments and partly by the Empire Marketing Board. The following are the annual contributions which are being paid at present: Tanganyika £4000, Kenya £1200, Uganda £1200, Zanzibar £1200, Northern Rhodesia £200, Nyasaland £200. The Empire Marketing Board is expected to make a maintenance grant up to one-third of the running costs of the Institute, but it will not exceed £6000 in any one year, and is subject to reconsideration after a period of three years.

THE Colonial Secretary appointed a committee last June, under the chairmanship of Lord Lovat, to make recommendations for the formation of a Colonial Agricultural Scientific and Research Service for the British Empire, in accordance with the recommendations of the Colonial Office Conference (NATURE, June 4, p. 824). This committee has now issued its report (Cmd. 3049. London: H.M. Stationery Office. 9*d*. net). It is recommended that the proposed Service should include both agricultural and specialist officers. It should be created immediately and recruited from officers of proved attainments in the field or laboratory. The formation of a Colonial Advisory Council of Agriculture and Animal Health, with two committees, dealing with agriculture and animal health respectively, is suggested. Each committee, and also the Council, should be composed of a representative of the Colonial Office, the director of the Imperial Institute, an agriculturist with tropical experience, and other technical and scientific officers, with a lay chairman. The duties of Council and committees would be to attend to the supply of agricultural and scientific officers for Colonial agricultural services, the establishment and direction of central research stations, and the direction of the main agricultural research policy of the Colonial Empire, the collection and distribution of information in fields not already served, and so on.

IT is particularly interesting to note that Lord Lovat's committee recommends salaries of £2500 and £2000 a year respectively for the chief and the assistant agricultural adviser for the new Service. It is considered that the chief adviser should be a distinguished man of science of proved administrative and organising ability, and it is hoped that the creation of a stable Colonial Agricultural Service, and including in it a grade with a maximum salary of £3000 a year, will attract and retain the ablest men. The cost of the new Service is estimated as £58,000 for the agricultural side, £35,000 for the specialist side, £14,000 for the Advisory Council, and £20,000 for one central research station, to be met by a cess of 1/400 on the revenues of Colonies with agricultural interests and a contribution of about £16,300 from the Empire Marketing Board.

WE have received the first *Annual Report of the Pure Rivers Society*, which was founded last October with the object of aiding landowners and others to bring actions to restrain pollution of rivers and inland waterways, and to give weight to representations for the same purpose. The objects of the Society appear to coincide with those of the Standing Committee on Rivers Pollution, which has done much during the last seven years to check the increasing pollution of the rivers of Great Britain and to bring a serious and growing abuse before the notice of the public. In a leaflet on "River Destruction" by this Society, it is pointed out that sufficient knowledge is available, without further research, to deal satisfactorily with many noxious effluents which are allowed to flow direct into streams. Although cleansing some of our most polluted rivers which pass through industrial cities may be beyond hope, it is abundantly clear that action under existing law would suffice to improve materially the condition of many other rivers without imposing great expense upon the various undertakings required to render their effluents harmless. In most cases the cost of taking such action precludes landowners and riparian authorities from exercising their legal rights, and the Government has been shy of imposing directly upon industries the financial burden of treating noxious effluents before emptying them into the rivers.

THE International Radio Communication Conference which was held last autumn at Washington was attended by 346 representatives from 79 countries. Almost every interest was represented, and the admission of representatives of the press was a departure from precedent which shows the tendency of the age. The general regulations which have been adopted were signed by all countries. The allocation of wave-lengths amongst the various services was one of the most difficult questions that had to be settled. Wave-lengths for ships' services had been previously dealt with at the London Conference in 1912. The further questions considered were in connexion with fixed services, aircraft services, broadcasting services, and commercial and amateur experimental services. Services between fixed stations will have to work on wave-lengths between 30,000 metres and 3000 metres, that is, with waves the frequencies of which lie between 10 and 100 kilocycles. The band between 3000 m. and 1875 m. is for the mobile services, that is, for ships, aircraft, motors, etc. The 2400 m. to 2000 m. wave-band is exclusively for ships' services; that between 2000 m. and 1875 m. is shared between fixed services and broadcasting services. In Europe the range between 1875 m. and 1550 m. is to be used for broadcasting services only, that from 1550 m. to 1340 m. for broadcasting and air services, and that from 1340 m. to 1050 m. for air services only. Waves from 1050 m. to 545 m. are assigned to mobile services, those from 950 m. to 850 m. being for air services only. The S.O.S. wave-length remains as at present, 600 m. Waves from 545 m. to 200 m. are for broadcasting services. For small ships a wave-length of 220 m. can be used. Waves from 200 m. to 5 m. are split up into bands for all services. The band 10·7 m. to 13·1 m. has been left unreserved. It is gratifying to find that a truly representative international conference, after a very thorough and lengthy discussion, has come to a fairly satisfactory solution of a most difficult technical problem.

IN the Faraday lecture given to the Institution of Electrical Engineers on Mar. 1, Dr. S. Z. de Ferranti emphasised the utilitarian value of applied electricity. He pointed out the importance of relieving as much as possible the present routine drudgery of work in the home. The traditional mechanical aptitude of Englishmen has been fostered by the advent of the motor-car, and radio receiving has fostered an interest in electrical matters which will be extremely helpful, as motors and other electrical devices are used more and more widely in the home. The ever-extending use of alternating current supply has brought prominently to the front the many advantages that would accrue provided we could store electric energy delivered by alternating current in a similar way to that provided by the lead storage cell for direct current supply. He pointed out, however, that there is nothing easier than to convert electricity into heat, and that this heat can be stored in water. The most important requirement of the household at the present time is low-grade heat in the form of hot water. Electrical engineers ought to advocate strongly this application of electricity. As to the future, he regarded electricity as the only means of regenerating the agricultural industry in Great Britain, taking into consideration the small acreage available and the need for the most intensive culture. He also visualised the wonderful results that would ensue if some concentrated form of storage after the manner of the lead storage battery, but without the drawbacks of its weight and cost, were invented. It would do away with the internal combustion engine, with the steam locomotive, and even with the steam turbine on board ship. He hoped also that in the future the Faraday lecturer, instead of having to give the lecture five times in different parts of the country to individual audiences, would be able to broadcast it to them all, and at the same time keep in touch with each meeting.

Dr. R. S. Clay delivered his presidential address to the Optical Society on "The Stereoscope" on Mar. 8. He stated that it was Sir Charles Wheatstone who first conceived the idea of presenting a pair of stereoscopic drawings to the right and left eye respectively, so producing the illusion of an object in relief. From a letter written by R. Murray, of Messrs. Murray and Heath, it was proved that Wheatstone had apparatus made for this purpose, using both prisms and mirrors, so early as 1832, though his actual paper, "Contributions to the Physiology of Vision," was not presented to the Royal Society until 1838. In 1840, Wheatstone had induced Fox Talbot (one of the inventors of photography) and Collen (one of its first exponents) to use the new art for taking stereoscopic pictures. Brewster in 1849 devised a more convenient, lenticular instrument, which was introduced and popularised through the agency of Duboscq at the time of the 1851 Exhibition. By the courtesy of the Delegacy of King's College, London, several of Wheatstone's original stereoscopes were exhibited. Among these was a 'moving picture' apparatus, in which a series of stereoscopic pictures of a French soldier presenting arms, mounted on a drum, was rotated by an ingenious intermittent motion. There were also a large number of early stereoscopes loaned from the Science Museum. These included a beautiful example of Swan's 'Cube' from the Court Collection, in which, by the combination of two stereoscopic pictures on the back and side of the 'cube,' an image of a lady appears in stereoscopic relief within the glass. Two original Wheatstone pseudoscopes were shown, by which a rotating glass beaker suspended from a string viewed from one direction appears to be changing its shape as it rotates; while from another direction it appears to be turning over and over about a horizontal axis, when it is really rotating about a vertical one.

Mr. A. D. Richardson (*Scot. For. Jour.*, vol. 41, pt. 2) has discussed in an interesting paper the value and quality of the Scots Pine in the north of Great Britain. We are not in full agreement with the writer in his opening statement: "While coniferous timber of such fine quality as that grown at higher latitudes—in Finland and Northern Russia, for example—cannot be produced in this country . . ." The difference in quality of timber may be attributed, we believe, primarily to the fact that our present day Scottish pine is chiefly of plantation and planted origin. The timber from natural seedlings growing in close canopy will always be superior to that from the ordinary type of plantation seen in Great Britain. In making this statement it may be admitted that the slower the growth the finer the quality of timber. That the opinion here expressed is held in expert timber quarters is supported by the following extract from the *Timber News* of Jan. 20: "It is not generally known [the writer presumably refers to trade circles] that the so-called fir or pine wood that is sent to London and other markets in large quantities from Baltic ports is no other than the produce of our native Scotch pine grown under more favourable conditions than are generally to be found in this country. For almost all classes of work this Continental wood is largely in use, such as road paving, building construction, and in the manufacture of small wooden ware of various descriptions. In a few districts of Northern Britain, notably Aberdeenshire, timber of the native pine is produced of quite as good quality as any that is forwarded from Norway, Sweden, or Russia, as was noticed and commented upon by the Canadian wood-fellers during the War." Mr. Richardson's article is chiefly concerned with a remarkable letter, bearing on the Scots pine and its development, which was written by Mr. James Farquharson, of Invercauld, on June 22, 1775, and sent to Dr. Hunter, F.R.S., the editor of the new (York) edition of John Evelyn's "Sylva" published in 1786. Farquharson's remarks with reference to planted and natural pine are worth reading and acting upon if we are ever to reproduce Scots pine to rival the naturally grown forests of Scandinavia and northern Russia.

Sheets of metal so thin that ordinary type can be read through them are now available as the result of research by Dr. Carl Mueller, of the Charlottenburg Laboratory, Berlin. His method of preparing them is to electroplate the metal on the surface of some soluble substance, such as rocksalt, and then dissolve away the support. A ring of thicker metal can be used to support the films, of which two and a half million would have to be piled to make a stack an inch high. Such films have been made of iron, nickel, gold, silver, and platinum, and it is found that although the nickel is much less transparent to visible light than gold, it readily transmits the shorter ultra-violet rays. The films are very elastic, and will bulge out for as much as a tenth of their diameter without breaking. Another curious thing about them is their high electrical conductivity. As these films are practically all surface, a strip of film containing no more metal than in a round wire one-hundredth of a millimetre in diameter will carry enough current to light several lamps; if the same current were passed through the wire, the latter would be instantly melted. This film may find use in radio and phonograph reproducers, since ordinary diaphragms are so heavy that they dampen some of the overtones and so coarsen the sounds.

The fourth International Congress of Entomology will be held at Cornell University, Ithaca, N.Y., on Aug. 12-18 of this year, with Dr. L. O. Howard as president. Invitations to send delegates have been forwarded to foreign governments through the State Department at Washington, and a programme is being arranged which provides for every important interest, educational, scientific, and economic. The mornings will be reserved for papers of more general interest, and during the afternoons, sections will deal with taxonomy, distribution and nomenclature, morphology, physiology and genetics, ecology, medical and veterinary entomology, and economic entomology relating to forest, field, and garden, bees, insecticides, and appliances. On an all-day visit to the Geneva Experiment Station, demonstrations of methods of spraying by machinery and dusting by aeroplane will be given, and immediately after the Congress, excursions are planned to the Niagara Falls, entomological museums of eastern cities, and laboratories of the U.S. Bureau of Entomology. [Cornell being the Alma Mater of a very large number of American State entomologists, and Dr. L. O. Howard the organiser of the U.S. Bureau of Entomology, a model for other countries, the attendance of American entomologists will be very large. Various European governments and institutes have already intimated that they will send delegates, and it is sincerely to be hoped that Great Britain likewise will be well represented at the meeting. The great difficulty for Europeans is the question of expenses. In order to obtain certain facilities of travel and to reduce the expenses, it is proposed to arrange for a party to travel together. Particulars of the party can be obtained from Dr. K. Jordan, Zoological Museum, Tring (Herts), the permanent secretary of the International Congresses of Entomology.

Any technical man who cares to peruse the advertisement pages of almost any technical publication, and then compares such advertisements with those in the general press, must surely be convinced that engineering propaganda is not conducted so effectively as it ought to be. In fact, nearly all technical advertisements look alike, except for the change in illustration and manufacturer's name. In the United States, technical propaganda is conducted with much greater effect, and that explains, perhaps, why Americans are capturing markets that were once British strongholds. Now anything that will advance any branch of science—and 'technical' advertising is a highly specialised science—is welcome. In "The New Propaganda in Industry," a booklet written jointly by a thoroughly trained technical man and an advertising consultant, and published by The Technical Advertising Service, Fitzalan House, Arundel Street, London, W.C.2, entirely novel considerations are brought to bear on this vital problem. Such questions as the nature of the thing to be advertised, how influence is established, the importance of a good policy, and the practical measures for giving effect to the psychological points which are even more important in industrial propaganda than they are in general publicity, are discussed in a way that must appeal to all those who have technical products to market.

The managers of the Royal Institution have appointed Dr. Alex. Muller to be assistant director of the Davy Faraday Research Laboratory. Dr. Muller is the author of a number of notable papers on the analysis of crystals, particularly the long chain compounds, which have been published in the proceedings of the Royal and other scientific societies.

At the annual general meeting of the Society of Public Analysts on Mar. 7 the following officers for the year 1928 were elected: *President*, Mr. Edward Hinks; *Vice-Presidents*, Mr. John Evans, Mr. Thomas Macara, Mr. John White; *Hon. Treasurer*, Mr. E. B. Hughes; *Hon. Secretary*, Mr. F. W. F. Arnaud.

The earthquake which is reported in the daily press to have caused some damage in the south of Italy was recorded at Kew Observatory on Mar. 7, at 10 hr. 59 min. 7 sec. G.M.T., as a well-defined shock. The records show that the epicentre was at a distance of 1250 miles in a south-easterly direction from Kew Observatory, and therefore probably in Sicily. Oscillations persisted for half an hour. A shock was also registered on Mar. 7 at 23 hr. 3 min. 31 sec. G.M.T. The epicentre is estimated to have been 4000 miles from Kew Observatory.

A very large earthquake was recorded at Kew Observatory on Mar. 9 at 18 hours 18 mins. 35 secs. The distance of the epicentre is estimated to have been 6200 miles away. Oscillations persisted for more than three hours. A message received at Kew from Bombay states that the distance of the shock from that station was 1880 miles. Combining these estimates, it appears that the earthquake must have originated either in the Indian Ocean or in the north of Sumatra and at about midnight local time.

Some popular lectures on scientific subjects are being delivered at the Polytechnique, Regent Street, London, in support of the King Edward's Hospital Fund for London. On Mar. 9 Prof. Julian Huxley lectured on the habits and behaviour of ants; and there will be a lecture on beam wireless by Mr. T. L. Eckersley on Mar. 23, and one on liquid air by Mr. A. J. Philpot on Mar. 30—both with experimental illustrations. Tickets (2*s*. 6*d*. and 5*s*.) may be obtained at the doors or at any of Messrs. Keith Prowse and Co.'s offices. Parties of not less than ten from schools are admitted at half-price.

The following nominations for office in the Chemical Society have been made, and the fellows thus nominated will be declared elected at the next annual general meeting: *President*, Prof. J. F. Thorpe; *Treasurer*, Dr. T. Slater Price; *Secretary*, Prof. T. S. Moore. The retiring president, Prof. H. Brereton Baker, will deliver his presidential address, entitled "Constitution of Liquids: Some New Experiments," at the annual general meeting to be held at Burlington House on Thursday, Mar. 22, at 4 P.M., and the anniversary dinner will be held the same evening at the Hotel Victoria at 7 for 7.30 P.M.

It is announced by the Natural Resources Intelligence Branch of the Department of the Interior at Ottawa that it has been decided to name the highest peak in British Columbia (13,260 feet) after Dr. G. M. Dawson, the well-known geologist on whose work the chief knowledge of the geology of British Columbia is based. Dr. Dawson was for several years director of the Geological Survey of Canada, and in the course of his work made a detailed examination of more than 6000 square miles of the interior of British Columbia. The exact location of Mount George Dawson given by the Provincial Government Surveys Branch is Lat. 51° 22′ N. and Long. 125° 16′ W., which is about 175 miles north-west of Vancouver and near the head of Knight Inlet.

IN an article in the *Chemiker Zeitung* for Feb. 11, by Prof. Haber, attention is directed to the fact that exactly twenty-five years have elapsed since the late Prof. Birkeland and Dr. S. Eyde solved the difficult problem of producing nitric acid commercially from atmospheric nitrogen. The need for applying a high-tension discharge was of course known, but the many previous attempts to utilise such a discharge on the commercial scale were unsuccessful until Birkeland and Eyde employed the device of electromagnetic distortion of the arc. That this method of solving the problem of nitrogen fixation had in course of time to give place to the more practicable ammonia-processes, was inevitable on thermodynamical grounds. Nevertheless, the achievement of these two pioneers may be regarded as marking the beginning of a new era in industrial chemistry.

MESSRS. Dulau and Co., Ltd., 32 Old Bond Street, W.1, have just issued Catalogue No. 157 of books relating to botany. Of the 1300 works listed, many are choice and rare. The catalogue can be had upon application.

MESSRS. W. and G. Foyle, Ltd., 119 Charing Cross Road, W.C.2, have just issued a short catalogue of second-hand books of science, ranging over the subjects of botany, natural history (including ornithology and zoology), mathematics, and physics. Copies can be had upon application.

WE understand that the works by Sir Flinders Petrie noticed in NATURE of Mar. 3, p. 311, can be obtained from Lady Petrie, University College, Gower Street, London, W.C.1, at the following prices: "Glass Stamps and Weights," 31*s.* 6*d.*; "Ancient Weights and Measures," 52*s.* 6*d.*; or, the two works together, 63*s.*

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A laboratory assistant to the biochemist of the Glasgow Royal Infirmary—The Secretary and Cashier, Royal Infirmary, 135 Buchanan Street, Glasgow (Mar. 22). A junior chemist under the Lancashire and Cheshire Coal Research Association—The Director of the Association, College of Technology, Manchester (Mar. 23). A woman assistant lecturer in geography in the department of education of the University of Birmingham—The Secretary, University of Birmingham (April 28). A professor of biology in Canterbury College, Christchurch, New Zealand—The High Commissioner for New Zealand, 415 Strand, W.C.2 (April 30). A demonstrator in organic chemistry and a demonstrator in physics at Bedford College for Women—The Secretary, Bedford College for Women, Regent's Park, N.W.1 (April 30). A full-time teacher of rubber technology at the Northern Polytechnic—The Clerk to the Governors, Northern Polytechnic, Holloway, N.7. A test assistant for photographic work at the Royal Aircraft Establishment—A.269, Chief Superintendent, R.A.E., South Farnborough. A lecturer in geography in the Queen's University of Belfast—The Secretary, Queen's University, Belfast.

Our Astronomical Column.

EXTENT AND DURATION OF THE UNIVERSE.—Dr. J. H. Jeans delivered the Trueman Wood Lecture before the Royal Society of Arts on Mar. 7, its title being "The Wider Aspects of Cosmogony." He naturally dwelt rather fully on the recent researches by Prof. Shapley and Dr. Hubble on the distances of the globular clusters and spiral nebulæ, which have so amazingly widened our conception of the volume of space that is accessible to our largest instruments. He referred to the Einstein view of space re-entering on itself, and concluded that the re-entrant region is not distant more than a thousand times the distance of Hubble's farthest nebulæ, which are at an estimated distance of 140 million light-years. Assuming that the whole of Einstein space is filled with nebulæ as densely as the portion surveyed, he estimated the number of stars in it as 2×10^{24}; he noted that the same number of grains of sand would suffice to cover England with a layer hundreds of yards in depth.

Dr. Jeans introduced some of his own conclusions on the interior of stars. He postulates that the central regions are liquid rather than gaseous, and thinks that this view explains the fact that stars tend to divide themselves into standardised sizes according to the number of rings of electrons left round the nucleus of the atom; the number may be 0, 1, 2, or 3, but cannot be fractional. Stars like Betelgeuse are concluded to have three rings left, while the small dwarf star discovered by Van Maanen has none left. He conjectures that elements exist in the central regions of the stars of higher atomic weight than any known on earth; this would explain the enormous amount of energy that they contain, which is able to keep stars shining for millions of millions of years. A few points in the lecture would not meet with universal assent, but it gave a very graphic picture of the vastness of the universe and its immense duration. Dr. Jeans tries to estimate the past duration in several different ways; they all give periods of the order of five to ten millions of millions of years.

COMETS.—*Popular Astronomy* for February contains a photograph of Encke's comet taken by Prof. van Biesbroeck at Yerkes on Jan. 21; it had a sharp nucleus and a broad tail 5′ long pointing westward; the present is the thirty-seventh observed apparition of Encke's comet; it has not been missed once since 1819. Comets Stearns (mag. 12½), Schaumasse (mag. 15), and Schwassmann-Wachmann (mag. 17) were also observed in January at Yerkes or Bergedorf; there seems to be no doubt now that the last-named comet passed perihelion in 1925; this brings up the number of perihelion passages of comets in 1925 to eleven, which is the greatest number on record; 1898 had ten.

NOVA PICTORIS.—This nova, like many recent ones, has now developed a nebulous ring round it. *Harvard Announcement Card, No. 55*, states that Prof. Hartmann at La Plata describes it as being 1′ in diameter; Mr. Paraskevopoulos, of the Boyden Station, Bloemfontein, notes that the nova is surrounded by a rather narrow well-defined ring of low density and small diameter; it was photographed with a Metcalf triplet, 10 cm. in diameter. Fuller details are promised in a forthcoming *Harvard Bulletin*.

Research Items.

Society Islands Technology.—Some interesting points in relation to the decay of native arts emerge from a study of handicrafts of the Society Islands, by Willowdean Chatterson Handy, which appears as *Bulletin 42* of the Bernice P. Bishop Museum of Honolulu. The processes studied are plaitwork, including basket making, matting, and braiding, and cord, rope, and net making, the preparation of material as well as the actual methods of making up being examined. The practice of these arts appears now to be identical in all the islands, but at one time there is no doubt that they could have been studied at each of the eight islands as local variants of a parent stock. Old objects are assigned to their place of original manufacture; for example, an old mat is recognised as from Maupati. Certain localities, however, are still recognised as having specialities. The manufacture of *tapa* has disappeared even in households which still carry on the native arts and crafts as part of the daily routine. The art of plaiting, on the other hand, is widely practised owing to the introduction of the making of straw hats by the missionaries in 1820. These, however, are worthy of record, as some of the plaits were formerly used in decorative plaiting on houseposts. On the other hand, the introduction of the sale of oranges in the markets of Papeete has led to the preservation of the nets once used for carrying or hanging bowls or gourds.

Sickness in Humid and Non-humid Weaving Sheds.—The Industrial Fatigue Research Board in Report No. 8, has published some valuable data on artificial humidification in the cotton-weaving industry, by Mr. A. Bradford Hill (London: H.M. Stationery Office). For the successful weaving of certain classes of cloth it is maintained that a high degree of humidity is necessary, and so the natural humidity of the air is increased by injecting additional moisture into the air of the weaving sheds in the form of steam. There has been strong opposition to the practice from the operatives, and several parliamentary inquiries have been held with resulting statutory regulations. It is claimed that the effects of working in these humid sheds is to lower the state of the operative's health. This report aims at determining what is the difference actually in sickness between the workers in humid and non-humid sheds. The weaving sheds chosen were situated in five Lancashire towns, in three of which sheds of both types were to be found; in one only 'dry' sheds, and in one only 'wet' sheds. In all, seventy-four firms took part in the inquiry; the number of separate sheds was 128, and the number of weavers concerned more than 20,000. The sickness history was obtained from the National Health Insurance approved societies. A year's investigation of the sickness incidence revealed no significant difference between the two types of sheds either in the number of days of sickness experienced, in the number of claims made, or in the number of persons suffering from one or more sicknesses. Analysis according to the *nature* of the incapacity suffered in the two environments yielded no evidence of any consistent or distinct differences in the distribution of specific sicknesses between the humid and non-humid sheds.

A Cirripede Parasite from the Dogfish.—The Report for 1926 of the Lancashire Sea-Fisheries Laboratory at the University of Liverpool and the Sea-Fish Hatchery at Piel, contains much that will interest both marine biologists and zoologists. Besides a number of small papers there are two which, both on account of their greater size and their considerable intrinsic interest, command attention. Prof. J. Johnstone and Miss W. E. Frost contribute a valuable paper on the general morphology of *Anelasma squalicola* (Lovén) which considerably advances our hitherto meagre knowledge of this very interesting cirripede parasite which they obtained from the dogfish, *Etmopterus spinax*. The fish were caught on the hake grounds off the south-west of Ireland at depths of about 150-180 fathoms, and some 5 per cent. of them were infected with the parasite which was rooted in the dorsal muscles. The paper contains a detailed account of the morphology of the parasite, well illustrated with clear, though somewhat diagrammatic, figures. Though mouth parts are present, only smaller than in the free-living cirripedes, the tubules of the 'digestive gland' in the one adult specimen examined showed signs of degeneracy, and the authors are inclined to agree with Broch that some part, at any rate, of the food is obtained from the host fish by way of the roots, which were originally exclusively organs of fixation. On the disputed point of the cement glands, they are of the opinion that these are derived from the original germinal material and that the cementing matter, no longer required for its original purpose, is modified to provide a portion of the food yolk in the mature eggs. The other important paper is by R. J. Daniel and is concerned with "The Abdominal Muscular Systems of the Common Shrimp (*Crangon vulgaris*)." The muscles are described and illustrated in minute detail, and their function in causing the backward spring, so important in the life of decapod Crustacea, is clearly demonstrated. It is a paper impossible to summarise here owing to its nature. Congratulations are due to Mr. Daniel for his highly successful treatment of a very difficult piece of work.

New Indian Trematodes.—Dr. E. C. Faust reports (*Records Indian Mus.*, vol. 29, pp. 215-218, 1927) on a unique holostome, about fifty specimens of which were collected from the intestinal tract of a holothurian (*Actinopyga mauritiana*) in the Andaman Sea. The most remarkable feature in the structure of this worm, which is designated *Cleistogamia holothuriana* gen. et sp. nov., is the entire absence of cirrus, genital atrium, and uterine opening. At the posterior end of the seminal vesicle, where a genital pore or a cirrus-sac might be expected, the vesicle bends abruptly forward and becomes constricted into a hollow filament which is continuous with the vagina. This apparatus therefore permits the transference of spermatozoa from the seminal vesicle directly into the vaginal sac. "The process here involved is not merely self-fertilisation; it is obligatory self-fertilisation or cleistogamy." The egg bears a long terminal filament, frequently coiled on itself like a watch-spring, which may either serve in rupturing the blind uterine sac, thus allowing dispersal of the enclosed eggs, or it may serve to entangle and fix the egg after discharge. This appears to be the first trematode recorded from a holothurian, and it is further exceptional in that the adult form occurs in an invertebrate. Dr. Faust remarks that the only other mature trematode in an invertebrate is Aspidogaster. S. C. Verma describes (*Op. cit.* pp. 139-156, 1927) a new species of Opisthorchis—only the second species of this genus known from fishes. This species (*O. pedicellata*) was found in the gall-bladder of the siluroid fish *Rita rita*, collected in the rivers Ganges and Jumna, about half the fish being infected. The characters by which *O.*

pedicellata may be differentiated from its nearest relatives are pointed out, and appended is a key to the species of Opisthorchis.

Nictitating Membrane of Birds and Mammals.—Mr. E. P. Stibbe (*Jour. Anat.*, 62, 159-176; 1928) has investigated the homologies of the so-called nictitating membrane of birds and mammals, and concludes that the plica of man and mammals differs entirely from the nictitating membrane of birds both structurally and functionally, and that there is reasonable ground for supposing that it is morphologically different also. He proposes to substitute the term *plica intercipiens* for the so-called nictitating membrane of mammals. The author hopes by a study of the ontogeny of the plica in mammals to elucidate its true morphology.

Branching in the Oil Palm.—A most remarkable case of branching in this palm (*Elæis guineensis*) is recorded by M. T. Dawe in the recent issue of the *Kew Bulletin of Miscellaneous Information* (No. 1, 1928). The palm in question is at Sierra Leone, is supposed to be more than a hundred years old, and has never been known to bear fruit. It branches very abnormally at a height of six feet or so from the ground, and sends out and up from a kind of fasciated growth eight normal-sized branches which attain a normal height. A further remarkable feature is that two of these branches have also branched. In many cases branching or forking in palms is due to injury or destruction of the growing point. The author finds it difficult to believe that the branching in this case is due to accidental causes, since the repeated branching would seem to indicate a physiological character. He would be interested to learn if any other cases of branching in the oil palm have been met with in any other part of West Africa or elsewhere.

Periodical Flowering of Bamboo.—In the *Japanese Journal of Botany*, vol. 3, No. 4, Seiichi Kawamura analyses the problem of periodicity in the flowering of the bamboo. The brakes come into flower at intervals of many years, the phenomenon occurring universally and simultaneously in the case of all brakes of the same species, even though situated in different provinces of Japan and in different latitudes. Different species, however, come into flower at different periods. The period of flowering seems to be unrelated to the age and extension of the brake, the thickness of the aerial stems, the fertility and humidity of the soil, exposure to sun, or climate of locality. From incomplete chronological records, the author assumes that the species *Phyllostachys Henonis* flowers at intervals of 120 (occasionally 60) years. Other species of bamboo show a similar order of periodicity. From consideration of the vegetative propagation of the bamboo, carried out by means of subterranean organs, it is suggested that all members of one species originated vegetatively from one ancestor, and thus all individuals of that species would be ontogenetically of the same age. This would explain the simultaneous flowering, which is seemingly independent of external conditions.

Glaciers of Edge Island, Spitsbergen.—One of the main objects of the Cambridge expedition which spent August last year on Edge Island was to determine the extent of the ice on that land, for little is known of the island and the interior has not been explored. In a lecture on Feb. 20 to the Royal Geographical Society, Mr. H. G. Watkins pointed out that the ice-covered area is horse-shoe in shape, surrounding the central unglaciated valley which lies in the south-west, at the head of Deevie Bay. On the south-east the ice-cap meets the sea in the well-known King John Glacier, which is an ice cliff more than twenty miles in length. On the south, and probably on the east, glaciers also reach the sea, but on the west and north no glaciers reach the coast. The scarcely known east coast was, however, not explored by the expedition on account of bad weather and lack of time. The ice-cap consists of large rounded domes, each about 1500 ft. in height, on which, in summer, there was the usual absence of snow. All the glaciers which do not reach the sea are retreating except one near the northern limit of the ice-cap; this is temporarily advancing. The bad weather prevented much survey being done by the expedition except on Deevie Bay and in the north-west of the island. It was even impossible to fix the position of Cape Heuglin in the north-east, the exact position of which is doubtful. The work that has been done is linked with the accurate work of the Russian Arc of Meridian expedition of 1899–1901 on the west and north coasts.

Indian Fossil Suidæ.—The fourth, and concluding, memoir of volume 8 of the Geological Survey of India contains Dr. Pilgrim's account of the fossil Suidæ. The wealth of the fauna is shown by the description of more than thirty new species distributed over many genera, seven of which are described for the first time. After an explanatory introduction, the memoir is devoted to a detailed account of the material, which is well illustrated by twenty plates.

English Eocene Mollusca.—The English Eocene Mollusca have long stood in need of revision under the light of modern researches and knowledge. This is now being undertaken by Mr. A. G. Wrigley, whose second paper comprising the Fusinidæ has just appeared (*Proc. Malac. Soc. Lond.*, vol. 17). A careful and critical systematic description of the genera and species is given with beautifully clear line drawings by the author himself of the more important of them. Grabau's hypothesis that the changes in the sculpture of a single gastropod shell as it develops from its protoconch to maturity indicate the history of the stock to which it belongs, comes in for severe castigation, and the author remarks that unfortunately Grabau's 'ancestral' forms are all too frequently preceded by their theoretical descendants.

Upper Cretaceous Cephalopods.—J. B. Reeside, jun. (*U.S. Geol. Surv. Prof. Paper*, 150B; 1927) gives a history of the views which have been held as to whether Scaphites is a natural or a polyphyletic group. Nine generic divisions have been proposed for Scaphites, of which the author accepts four as valid, namely, Scaphites (restricted), Desmoscaphites, Discoscaphites, and Acanthoscaphites, referred to the families Stepheoceratidæ, Desmoceratidæ, and Cosmoceratidæ respectively. A catalogue is given of all the specific names which have been applied to Scaphites, and the work concludes with a table showing the stratigraphical distribution of the species from the Upper Gault to the Maestrichtian. In another memoir, the same author (*ibid.*, *Prof. Paper*, 150A; 1927) gives an account of the cephalopods from the lower part of the Cody Shale, Oregon; he recognises a zone found in the Niobrara formation of the Great Plains, and considers that some of the species present strongly support the correlation of the Niobrara formation with the European Coniacian (Emscherian). Reeside (*ibid.*, *Prof. Paper*, 151; 1927) also describes and figures the cephalopods of the Eagle Sandstone, in which the principal genera represented are Baculites, Scaphites, Placenticeras, and Peroniceras.

Fluctuations of the Level of the Caspian Sea.—Prof. A. V. Voznesensky, who studied this problem on the spot very thoroughly, gives in *Priroda* (No. 10, 1927) a brief summary of his observations. The latter are based mainly, so far as ancient fluctuations are concerned, on the historical evidence, particularly with regard to a large building, a karavanserai, in the Baku bay. The building was erected in about 1135 A.D., of course on dry land, on a small hillock. In the interval from 1135 until the beginning of the eighteenth century, the building is not mentioned in any documents; this is understandable, since there exists trustworthy historical evidence that in 1306 Baku was flooded by the sea, which reached a mark about 16 metres above the level of 1135. From the fifteenth and sixteenth centuries there are historical records of the sea receding again, and about 1723 the top parts of the karavanserai appeared from the water. Towards the middle of the eighteenth century the level of the sea rose again almost to the level of the fourteenth century; since then a series of smaller fluctuations has followed, but on the whole the waters have receded, and in 1925 even the foundations of the building became visible. The reason for these fluctuations is partly in the climatic variations (Bruckner's periods), but mainly in the seismic disturbances. The practical importance of the fluctuations is obviously great, since even a small lowering of the level affects navigation and fisheries in the whole of the Caspian Sea, and this makes a detailed study of the problem highly necessary. A survey was carried out on the Apsheron peninsula in 1911–12 by the Seismic Commission of the Russian Academy of Sciences, and it is to be hoped that another will be undertaken shortly which should give valuable data on the problem.

Quartz Resonators.—The use of quartz resonators as standards for measuring frequency, and also for stabilising the frequency of radio circuits in connexion with radio communication, is rapidly extending. Prof. Cady, of the Wesleyan University, Connecticut, made very valuable researches on the piezo-electric behaviour of small plates of crystalline quartz in 1922. In 1923, Dr. D. W. Dye pointed out that there appeared to be a field of usefulness for quartz vibrators as frequency standards and as frequency stabilisers. Since then, progress has been very rapid. In a paper read to the Institution of Electrical Engineers on Mar. 7, by G. W. N. Cobbold and A. E. Underdown, many practical developments carried out by them at the Army laboratory at Woolwich are described. They show that there is a very simple relationship between the dimensions of the quartz oscillator and the frequency produced. They point out that the frequency is very little affected by the temperature of the quartz. The temperature coefficients found experimentally were less than ten parts in a million per degree Fahrenheit. The other standards used for the determination of radio frequency are an oscillatory electric circuit consisting of an inductance associated with a capacity or an elinvar tuning fork. The latter, when associated with a multi-vibrator, can be made to provide a series of standard points in the band of frequencies used in radio work. The materials used in the construction of the electro-magnetic standard do not retain their permanence in the way that elinvar and quartz do, and their temperature coefficients are higher. The authors consider that for national and international standards of the highest quality the fork is the best. There is, however, a wide field for quartz resonators as secondary standards, especially in short-wave radio practice. In this case the frequencies are enormously high in comparison with the frequency of a tuning fork. The authors describe a crystal multi-vibrator which gives a series of frequencies from 2000 to 15,000 kilocycles per second, that is, from 150 to 20 metres in wavelength, in multiples of 1000 kilocycles per second.

Geometrical Optics.—In his presidential address to the Optical Society in February (*Transactions of the Optical Society*, vol. 28, Pt. 5) Mr. T. Smith dealt with the futility of the present methods of teaching geometrical optics. The well-known diagram of rays incident on one of the principal planes of an optical system and emerging from the other principal plane he characterises as "elegant" but "trivial," and "inconsistent with the known properties of light." As a basis for a more accurate and real geometrical treatment of the subject, he shows that when a ray of light travelling in air falls on the surface of a sphere and is refracted, a straight line drawn through the centre of the sphere to cut both rays cuts them in conjugate points, and that if the triangle formed by the rays and the radius be swung about the centre of the sphere, the ends of the radial line describe concentric arcs which are object and image with constant magnification. From this he shows that the surfaces of constant magnification for either a single refracting surface or for a lens can be easily and accurately drawn. It is to be hoped that these methods will soon find their way into elementary text-books.

Slag, Coke Breeze, and Clinker as Aggregates.—The Building Research Station of the Department of Scientific and Industrial Research is carrying out work to determine the cause of failures occurring with concrete made from materials such as furnace clinker, and in Special Report No. 10 (London: H.M. Stationery Office) F. M. Lea and F. L. Brady summarise present knowledge on this subject. The composition of acid and basic slags, breezes, clinkers and cementing agents is discussed, and the factors affecting the suitability of these materials for various uses are considered. Slag forms a good concrete provided that it is not very acid or strongly basic, but coke-breeze-concrete is apt to be mechanically weak and is therefore only suitable for inside walls. This is due to the fact that coke-breeze is often contaminated with coal or may have a high sulphur content, in which case weathering causes oxidation of the calcium and iron sulphides to the sulphates with increase of volume. Clinker suffers from the same disadvantages and usually fails on account of the presence of unburnt coal. The methods of utilisation of these materials are discussed, and it is concluded that slag concrete can be made having a strength at least as great as that of gravel concrete. Clinker concrete is not so strong, but is better than that made from breeze. The report includes a bibliography of the more important papers on the subject.

The Salting-out Effect.—The influence of electrolytes on the solubility of *m*-cresol in water has been studied by J. S. Carter and R. K. Hardy, who have described their work in the January issue of the *Journal of the Chemical Society*. The solubility s of a non-electrolyte in a solution of a salt of concentration c is known in many cases to be represented by the equation $s = s_0 e^{-kc}$ where s_0 is the solubility in the pure solvent and k is a constant which is a measure of the salting-out effect. This law has been verified for the effect of sodium and magnesium chlorides and sulphates upon *m*-cresol solutions, but does not hold if the free acids are used. The sulphate ion is much more efficient for salting-out than the chloride ion, and the solubility of *m*-cresol is lowered more by salts than by the corresponding acids.

The Russian Academy of Sciences and its Institutions.

THE Russian Academy of Sciences, representing as it does the highest seat of learning in all its branches in the State, consists of a large number of affiliated institutions, and a survey of them, recently published by the Academy,[1] is of wide interest to all men of science. The interest is not affected by the fact that the survey has been prepared for a specific purpose, namely, for the occasion of the tenth anniversary of the Soviet government, with the view of showing the world the effect that the Revolution has had on Russian science. The volume consists of a series of chapters dealing with each institution separately, and we will follow this arrangement. Each chapter concludes with a bibliography of papers and books dealing with the particular institution, and with a list of scientific and technical staff.

The Library of the Academy was founded by Peter the Great, who brought a number of foreign books home from his travels. At first it functioned as a public library, but with the foundation in 1812 of a special Public Library in St. Petersburg it was transformed into a purely academic library. In 1924 a new building was completed for the library, with a floor space of 12,500 sq. metres. The number of titles of books and manuscripts in the library is more than three millions; the staff numbers 170.

The Steklov Physico-Mathematical Institute developed from the first Russian scientific laboratory, apparatus for which was actually acquired by Peter the Great before the Academy was founded. At first it was called the Physical Laboratory, and amongst its directors have been E. Lentz, B. S. Jacoby, O. D. Chwolson, B. B. Galitzine. The last-named started highly important work on seismology, and it is due to him that the Russian seismological service was developed, but during the civil war and the Revolution it was almost wholly destroyed, and only now are steps being taken to re-establish it. The Physical Laboratory during that time also practically ceased to function. In 1921 the mathematical cabinet was founded under the directorship of V. A. Steklov, and in the same year it was united with the Physical Laboratory to form the present Physico-Mathematical Institute, which was named after V. A. Steklov when the latter died in 1926. At present the institute consists of three departments: mathematical, physical, and seismic; the present director is A. F. Joffé.

The Chemical Institute developed from the chemical laboratory founded in 1748 by Lomonosov, one of the first Russian chemists, and such well-known chemists as Frizsche, Zinin, Butlerov, and others have worked in it. In 1924 the laboratory was transformed into the Chemical Institute with two departments: general and organic chemistry, high pressures and high temperatures. In connexion with the Institute are working some of the institutes of the Commission for the Study of Natural Resources (see below). The department of general chemistry under N. S. Kurnakov is working at present mainly on problems of physico-chemical analysis, pure and as applied to the study of ores and minerals. The second department, under V. N. Ipatiev, is studying the action of high pressures and temperatures on chemical compounds.

The Dokutchaev Soil Institute began its activities in 1881 as an independent public committee under V. V. Dokutchaev and later under K. D. Glinka, who has recently died (*v.* NATURE, Dec. 17, 1927, p. 887). Since 1918 it has been incorporated into the Academy, and at present it consists of a soil museum, department of soil cartography, department of soil surveys, and a department for the study of the dynamics of soil formation.

The Physiological Institute was founded in 1889 as a laboratory, and is at present under the directorship of I. P. Pavlov; its work is mainly on the problems of reflexes, and the physiology of brain generally.

The Yafetic Institute is one of the recently founded (1921) branches of the Academy, and its work consists in research on Yafetic languages of the original population of Europe. The director of the Institute is N. J. Marr.

The Laboratory of Biochemistry and Plant Physiology has been in existence since 1889. Its present director is S. P. Kostychev, and the work is mainly concentrated on biochemistry of fermentation, photosynthesis, fixation of atmospheric nitrogen, and mineral nutrition of plants.

The Special Zoological Laboratory, founded by A. O. Kovalevsky in 1893, was considerably enlarged in 1921 under the directorship of N. V. Nasonov, and is working on different branches of morphology and experimental zoology.

The Geological Museum was originally a part of the *Kunstkamera* founded by Peter the Great. In 1913 funds were obtained for a large new building, but the War prevented its erection, and it was not until 1922 that the Museum obtained new premises for development. At present only some of the galleries are open to the public, but scientific work is being carried out in all directions, under the directorship of F. J. Levinson-Lessing.

The Mineralogical Museum originated in the same way as the Geological Museum. It has now six exhibition galleries and scientific laboratories guided by A. E. Fersman. During the last ten years numerous expeditions have been organised by the Museum for studying mineral resources of outlying parts of Russia.

The Botanical Museum was also founded by Peter the Great. There are no exhibition galleries, the Museum consisting entirely of herbaria, occupying twelve halls. Research work is being conducted mainly in the Caucasus, Siberia, and Northern Russia. The present director is I. P. Borodin.

The Zoological Museum has existed since 1832 as a special institution, and consists of public galleries and scientific departments, under the directorship of A. A. Birula. The scientific staff includes 35 workers. Expeditions for the zoological survey of various parts of Russia are being organised more extensively than in the past, and collections from the Palæarctic region are enormous in size. There are, however, difficulties in publishing the results of scientific work. Exhibition galleries occupy two large halls.

Pushkin House is a museum for preserving all relics connected with the great national poet, for scientific research on Pushkin, and on the history of Russian literature generally. It has a remarkable collection of manuscripts, a library, and public museum. The present director is S. F. Platonov.

The Museum of Anthropology and Ethnography again developed as a part of the *Kunstkamera*. It represents the central place for all research on anthropological and ethnographical problems, and consists of laboratories and public galleries, under the directorship of E. F. Karsky.

The Asiatic Museum is rather a library than a museum, since all ethnographical objects have been transferred to the corresponding museum, and the main aim of the Asiatic Museum is collecting and studying literature, both printed and manuscript, on oriental problems; it has probably the richest collection in the world on oriental studies. The Museum is under the directorship of S. F. Oldenburg.

---

[1] Scientific Institutions of the Academy of Sciences, U.S.S.R. Leningrad, 1927. Pp. 169+17 plates.

The Museum of Palæography was founded in 1925 and has as its aim a full representation of systems of writing, from the ancient inscriptions on monuments to the present-day printing technique. The Museum is still in course of organisation.

The Commission for the Study of Natural Resources was founded in 1915 on the initiative of its present president, V. I. Vernadsky, with the view of studying systematically the natural resources of Russia. The main directions of work are defined as: unification and consolidation of local work on the study of natural resources; independent field research; description of separate regions from the point of view of their resources; research in the practical utilisation of natural resources. In accord with its diversity of functions, the Commission has a number of working branches, as follow: Institute of Physico-Chemical Analysis, working on analyses of salt deposits in the Caspian Sea, metallic ores, etc.; Institute for the Study of Platinum and other Noble Metals, studying methods of analysis of platinum ores and the extraction of the metal from them; Section of Non-Metallic Minerals and Gems, which has published a series of monographs on asbestos, sulphur, etc., as well as on gems and valuable stones; Section of Stone Building Materials, which is studying building materials from the point of view of their distribution in Russia, and from the technical aspect as well; the Sapropelite Committee, which is engaged in studying lake deposits and their utilisation; the Gaseous Section, which studies natural gases, mainly from the point of view of the presence in them of helium for aviation purposes; the Section of Energetics is preparing a register of natural power resources, mainly of water, but also of wind and tides; the Geographic section is mainly engaged in research on problems of economic geography; the Bureau of Genetics studied at first problems of heredity in man, but at present it is engaged in work on heredity in wheat, domestic animals, etc.; Section for the Study of Living Substance, under V. I. Vernadsky, is engaged on problems of the influence of organic matter on geochemical processes; the Moscow section of the Commission has also several laboratories—for genetics, applied zoology, etc.

The Commission for the Study of Nationalities occupying Russia is studying the population, preparing maps, studying habits of various national groups, their occupations, etc.

The Commission for Scientific Expeditions is intended to correlate expeditions sent out by various institutions of the Academy. The number of expeditions has increased greatly during recent years, and for the last ten years (1917–1927) their number exceeded two hundred.

The Special Committee for the Study of Allied and Autonomous Republics was founded in 1926 in order to direct and co-ordinate surveys organised by the Academy at the request of republics. The committee is organising expeditions into Kazakstan (Kirghiz steppes), Karakum desert, Armenia, and other parts.

The Commission for the Study of the Yakut Republic was formed at the request of the said republic for a comprehensive survey of its natural resources. The work is calculated to take five years, and preliminary results have already been published.

The Commission for Science and Scientific Workers is preparing registers of all scientific workers in Russia, which it is intended to publish regularly.

The Polar Commission was founded in 1914 for co-ordination of work in polar countries done by different bodies. Its activities have developed only since 1923, and in 1925 an expedition to Novaya Zemlya was organised.

The Historico-archæographical Commission is dealing with the publication of historical documents and manuscripts on nationalities of Russia.

The Dictionary Commission has existed since 1922, and is preparing materials for a dictionary of the Russian language, which is being published.

The publications of the Academy and its institutions are produced in the Academy's printing office. Its publishing activities suffered much during the years of revolution, and at present the pre-War level is still not reached. Publications are distributed by the Academy book-store and the Bureau for International Exchanges. Interruption of exchanges was severely felt by the Academy, but at present exchanges are approaching normal.

The Glacial Retreat from Central and Southern Ireland.[1]

By Prof. J. K. CHARLESWORTH.

THE newer drift of Ireland is bounded on the south by a broad and well-developed kettle-moraine—the 'South Irish End-moraine'—which runs from the vicinity of Wexford round the northern flanks of the Dublin hills and by way of Baltinglass, Bennettsbridge, Cahir, Tipperary, Charleville, and Newcastle West to the mouth of the Shannon, a distance of 310 miles from coast to coast.

Contemporaneous with this stage of the Ivernian ice and the Irish Sea ice were the independent ice-centres in the Kerry and Wicklow Hills, the Comeraghs, Galtees, Knockmealdown, and other mountain clusters of the south. Their extent is likewise indicated by well-marked outer moraines, and corresponds to a snow-line on northern and eastern slopes of about 1000 feet and on other slopes of approximately twice that altitude.

The Irish glacial fauna is restricted, with but few exceptions, to the region outside these moraines.

The ice recession from the Dublin and Wicklow Hills is clearly shown by moraines and marginal drainage-features. These prove a pivoting of the ice on the northern slopes of the hills, immediately south of Dublin, and the sweeping of the ice-fronts to east and west, at successive stages of the retreat, in a series of curves which swing out of each other tangentially and northwards.

The dissolution of the Ivernian ice-sheet caused the emergence of the higher hills, such as the Castlecomer Plateau, the Slieve Bloom, and Keeper Hills, and the formation of large lobes protruded southwards down the intervening valleys. The moraines of the Barrow, Nore, Suir, Shannon, and other lobes are magnificently displayed, making possible the correlation from lobe to lobe and the delineation of the successive positions of the ice margin across the country from coast to coast. The festooning of the moraines in the southern part of the country is governed by the relief, while their sinuous form in the northern region is to be ascribed to the break-up of the ice-sheet into separate lobes, flowing on roughly parallel lines.

---

[1] Substance of a communication read before the Geological Society on Jan. 25.

The ice-sheet in its recession over southern Ireland remained pivoted on the Dublin hills, and retreated over ever-widening strips of country as the ice-front is followed westwards; a withdrawal of 65 miles in the west is represented south of Dublin by but a few hundred yards.

The ice retreating over the Central Plain was dissected into three perfectly distinct lobes, which centred upon the mountains of Donegal, Leitrim, and Galway respectively. Their stages of recession are indicated by countless moraines, the 'eskers' of Irish glacial literature True osar occur subordinately, transversely within, and as integral parts of, the kettle-moraines.

University and Educational Intelligence.

Cambridge.—The Royal Society and the Royal Geographical Society jointly have given to the Polar Research Institute a sum of money of about £200 arising from the sale of the reproduction of *The South Polar Times*, published after the return of Captain Scott's first expedition. Lady Walston has offered to the University a sum of £3000 to endow a studentship in classical archæology, to be called the Walston Studentship, in memory of her husband, Sir Charles Walston. The purpose is to facilitate visits to Greek lands for young graduates of either sex studying archæology and architecture.

Miss S. M. Manton, Girton College, has been appointed University demonstrator in comparative anatomy. Mr. E. P. Weller has been appointed University lecturer in estate management, and Mr. L. F. Newman, St. Catherine's College, University demonstrator in methods of agricultural analysis. Mr. G. F. Hickson, Clare College, has been appointed secretary of the Board of Extra-Mural Studies.

Grants have been made from the Worts Fund to Mr. J. A. Steers, St. Catherine's College, towards his expenses on the British Association expedition to the Great Barrier Reef of Australia and to Mr. H. Gilbert Carter, Trinity College, towards the expenses of a botanical survey of the Island of Madeira. Dr. G. Shearer, Clare College, has been nominated to use the University's table at the zoological station at Naples during the coming vacation.

The throwing open of practically all scholarships, studentships, and prizes to women students has led to the proposal which the Council of the Senate is making to the University, with the consent of the councils of Girton and Newnham Colleges, that the separate Harkness scholarships in geology for men and women shall be united into a single scholarship. The new scholarship will have an endowment of nearly £190 a year.

The *Annual Report* of the Appointments Board shows a marked increase in the number of appointments secured. The steady growth of graduate employment in industry in Great Britain is a marked feature in the year's work.

London.—The following doctorates have been conferred: D.Sc. in Chemistry on Mr. E. A. Fisher (Rothamsted Experimental Station) for a thesis entitled "A Study of Some Moisture Relations and Some Other Physical Properties of Soil, Clay, Wool, Cereal Products, and Some Other Colloidal Materials," and on Mr. D. H. Peacock for a thesis entitled "The Reactivity of Halogen Compounds and Other Papers," together with fifteen subsidiary contributions; D.Sc. (Engineering) on Mr. H. J. Gough, for a thesis entitled "The Manner, Causes, and Characteristics of the Failure of Metals under Static and Repeated Stresses," together with nine subsidiary contributions.

A course of three free public lectures on X-rays will be given at the Imperial College of Science and Technology by Prof. K. M. G. Siegbahn, of Upsala, at 5.30, on Mar. 20, 21, and 22. No tickets will be required.

Oxford.—The Report of the Curators of the Bodleian Library, presented to Convocation on Mar. 13, contains a matter of special interest to scientific men, namely, the record of the fact that early in the past year the Radcliffe Science Library became a department of the Bodleian. This new development may be regretted on historical and sentimental grounds; but, as the Report points out, the change is certain to lead to increased efficiency, both in the supply of scientific books and periodicals, and in the facilities offered to readers. A strong scientific advisory committee has been appointed to assist the Bodleian Curators in matters pertaining to the Library. The necessary work of reorganisation has been begun, but time and persistent effort will be required for its completion.

Under the will of the late Mrs. Emma Grace Marryat, who was interested in Messrs. Caird (Dundee), Ltd., jute manufacturers, of Dundee, a sum of £200,000 is to be set aside for the foundation of travelling scholarships in engineering, electricity, aeronautics, and music, to be known as Sir James Caird Travelling Scholarships, eligible to natives of Scotland only.

The spring meeting of the Geographical Association is to be held at Oxford on April 13-16. The proceedings will include a public lecture on April 14 by the Right Hon. Sir Halford Mackinder on "The British Empire in Relation to the Geography of the World," a lecture on April 16 by Colonel C. H. D. Ryder on "Surveys from Air Photographs," and a discussion on the same day, opened by Dr. L. Dudley Stamp, on "Practical Steps in Regional Survey Work and Local Studies." The address of the Association is 11 Marine Terrace, Aberystwyth.

The following appointments have recently been made by the British Research Association for the Woollen and Worsted Industries, Torridon, Headingley, Leeds: Mr. J. A. Fraser Roberts, senior assistant at the Animal Breeding Research Department of the University of Edinburgh, to be head of the Biology Department; Mr. Norman Tunstall, senior physicist at the Department of Physics, University College of Wales, Aberystwith, to be senior physicist of the Physics Department; and Mr. Claude Rimington, research scholar, Bio-Chemical Laboratory of the University of Cambridge, to be bio-chemist to the Association.

The sixteenth annual dinner of the Finsbury Technical College Old Students' Association was held on Mar. 2, when the chair was occupied by Mr. F. H. Carr, president of the Association. Prof. H. E. Armstrong, in proposing the toast of "The Association," said that Finsbury was the Technical College which Prof. Ayrton and he had started, to carry out the scheme of the City Guilds of London Institute; the curriculum was arranged at the beginning to provide the chemist with some understanding of engineering, and the engineer with some understanding of chemistry. The chemical engineer as produced to-day is neither chemist nor engineer; engineering should be left to the engineer. Finsbury decided at its outset never to touch Science and Art Department or other external examinations, whereas now everywhere examinations are the order of the day. The chairman in reply referred to Prof. Armstrong as the 'father' of Finsbury, who had throughout his life striven for the things which are so important, namely, first principles. Though the College has ceased to exist, its old students should continue to meet and to do what they could to further the principles for which it stood.

Calendar of Customs and Festivals.

March 18.

St. Cyril.—He succeeded Maximus as Patriarch of Jerusalem about 351 B.C. The most noteworthy event of his patriarchate in its effect on the church was the accession of Julian the Apostate to the Imperial throne in 361. At the time of his apostasy some ten years earlier, he had "washed off the laver" of baptism by a self-immersion in bull's blood. His last attack on Christianity was an attempt to rebuild the Temple and revive the Levitican sacrifices, a cause of great rejoicing to the Jews. The undertaking was brought to a stand by "fearful balls of fire breaking out near the foundations, which scorched the workmen." Then followed an earthquake, a whirlwind, fire from Heaven, a luminous cross in the air, and marks of crosses on the garments of the Jews.

St. Tetricus, Bishop of Langres, A.D. 572.—An incident during his ministration serves to illustrate the use of the Bible as a means of divination in the Christian church. Chramn, rebel son of Clothaire, wishing to be informed of the future, three books—the Prophets, the Gospels, and the Epistles—were placed on the altar in the church of St. John, Dijon, while the clergy and Chramn prayed. Each book was then opened. The unfavourable omens indicated by the passages upon which Chramn lighted were fulfilled by his defeat and death.

Sheelah's Day, in Ireland, when the shamrock should be worn as on St. Patrick's Day. Tradition is uncertain who Sheelah was; but popularly she was connected with St. Patrick, either as wife or mother. It is interesting that tradition should associate closely a festival in honour of a female with that of the saint, just as the festival of his mother follows immediately on St. David's Day. In Celtic religion a female deity was usually associated with a male deity, by whom she often came to be, more or less, superseded.

Mid-Lent.—The fourth Sunday in Lent, being the middle period of the fast (Mi-Carême), is still celebrated on the Continent by processions and rejoicings similar to those of Carnival. Some traces of the celebration represented in Mi-Carême also survived in Great Britain. At Bury, Lancs., this Sunday was known as Simnel Sunday, from the fact that people assembled in large numbers in the town and ate simnel cakes, and a general merry-making prevailed, usually with no little disorder, notwithstanding the day. The name of these cakes has been traced to the thirteenth century. It was usual for them to be stamped with a figure of the Virgin or of Christ.

Other names for this day are "Mothering Sunday," "Mulled Ale," and "Braggart Sunday." Mothering Sunday has been explained as the custom of visiting "Mother-Church" on this day and making a presentation on the high altar, or of visiting parents and making them a present of money, a trinket, or "some nice eatable." That these are mutilated survivals of a more significant observance is made clear when they are brought into relation with customs on Mid-Lent Sunday recorded elsewhere. In Seville, children appeared in the streets, fantastically dressed, making an incessant din and crying "Saw down the old woman." At midnight, parties paraded the streets knocking at every door and repeating the same formula. Finally, the figure of an old woman representing Mid-Lent was sawn in two. In Franconia the custom was known as "the Expulsion of Death" An image of straw was suspended on a pole and carried about from village to village, where either it was received with a feast for the bearers, or it was driven away. Sir James Frazer in "The Golden Bough" quotes a number of parallel observances, from which it is clear that the custom, which in England survived only as a merrymaking and feast, originally was a festival representing the death of winter, the figure in the end being burned or thrown into water; and the coming of spring, summer, or life, was represented by a green bough or tree, similar to the green boughs of May Day. This was carried in procession after "Death" had been "carried out."

March 19.

St. Laclean of Clonfert, A.D. 622.—His birth was announced by an angel fifteen years before it took place, while just before the event milk from his mother's breasts healed an old man of blindness. At his baptism no water was at hand; but Mohemath took the fingers of the babe and marked with them a cross on the earth and instantly a fountain burst forth. A grain used as an emetic by the people of the country served as his diet without ill effect. This may be a reference to a form of trial by ordeal from which the saint was exempt in virtue of his sanctity. During a murrain, the red cow which had provided the saint with milk survived to the last; but when the babe was taken to it in his mother's arms, it revived, and its milk being distributed among the other cows, they also revived. The life of this saint, it may be noted, is based almost entirely on oral tradition.

March 20.

St. Cuthbert, A.D. 687.—The great saint of northern England. A border legend relates that when, in accordance with the practice of Celtic saints, he sang his vigils up to his neck in the waves and afterwards on the sands, two otters came out of the water and restored animation to his frozen feet by licking them while he prayed. For long he lived on the desert island of Farne, which no one would visit because it was haunted by demons. The tameness of a species of aquatic birds found on this island only, and known as the 'Birds of St. Cuthbert,' is attributed to the fact that, taking them for his companions, he inspired them with a trust in man which their descendants have inherited. Certain little shells of the genus Entrochus are known as St. Cuthbert's beads, and it is believed that he can be seen seated on a rock by night, using them as his anvil.

St. Wulfram of Lens, A.D. 741.—Missionary to Friesland, where he laboured to suppress the pagan sacrificial rites. The victims were selected for sacrifice by the casting of lots among the children of the nobles. They were then hung on a tree as an offering to Woden, or fastened to a post between the tides and left to drown as an offering to Ran, the sea goddess, that she might not overflow the low-lying-land.

March 21.

St. Benedict, *b.* A.D. 480, *d* 543.—The initiator of the famous rule of the Benedictine Order, of whom many miracles are related. He was immune from the effects of both fire and poison When thrown into a hot oven he was still unharmed at the end of twenty-four hours. A poisoned cup broke to pieces when he blessed it.

March 23.

St Fingar, about A.D. 450, fled to Cornwall to avoid his father's wrath While travelling, the saint and his party were received at night by a pious woman, who killed her cow for their food. St. Fingar took the skin and put the bones in it, whereupon the cow rose up whole and began to low.

Societies and Academies.

LONDON.

Linnean Society, Feb. 16.—**E. Heron-Allen**: On the further researches of Joseph Jackson Lister, F.R.S., F.L.S., upon the reproductive processes of *Polystomella crispa* (Linn.). At the time when the late J. J. Lister's paper on the production of microspheric young by the conjugation of flagellispores emanating from the megalospheric form of *P. crispa* and other Foraminifera (read in 1894) was in process of publication, he was engaged at Plymouth in further researches, as a result of which he was enabled to establish the production of megalospheric young by viviparity in the microspheric form. He left a succinct account of his work in MS., which was read by Mr. Heron-Allen.—**M. A. C. Hinton**: False killer-whales (*Pseudorca crassidens*) in the Dornoch Firth. The school which entered the Dornoch Firth last October was a large one. Most of the whales were carefully measured, their stomach-contents examined, and parasites, internal and external, collected; practically all the females were dissected for information as to breeding. With the help of local labour the whales were flensed, and the skeletons prepared and dispatched to the Natural History Museum. A full-grown bull and a large cow were sent entire to London, where plaster casts were made from them. Numerous dissections have been made and 143 skeletons collected and cleaned.—**Mrs. L. Hunter**: Alcyonaria of the Abrolhos Islands. There are twenty-four species, eight of which are new and nine of which are represented by new varieties. Representatives of the order Alcyonacea predominate, the majority being species of the Nephthyidæ. The orders Stolonifera and Gorgonacea are represented, but Heliopora, usually abundant on other coral reefs of the Indian Ocean, is absent. The creeping membrane in the specimens of Xenia provides a link between the orders Stolonifera and Alcyonacea. The three species of Eunephthya supply a link between the lobose members of the Alcyoniidæ and the tree-like forms of the Nephthyidæ. The spicules found on *Sarcodictyon tropicale*, the first species of the genus to be recorded in warm waters, are of remarkable interest, since it has incorporated in some way the siliceous spicules of the tetractinellid sponge upon which the specimen is creeping.

Royal Statistical Society, Feb. 21.—**T. H. C. Stevenson**: Vital statistics of wealth and poverty. The method employed in the recently published Report of the Registrar-General on Occupational Mortality during 1921–23 is that of inferring social position from occupation. By this means regard can be paid to (average) culture as well as income, and the total occupied population can be included in the inquiry. Respiratory diseases, including phthisis, increase without interruption from a minimum in the highest to a maximum in the lowest social class. The process is reversed for diseases of the digestive system, and for diabetes in later life; mortality from appendicitis increases without interruption from a minimum for the lowest to a maximum for the highest of the five social classes distinguished. Mortality from cancer is lowest in the highest, and highest in the lowest, section of society; but this gradation applies to cancer of certain sites only, mortality from the remainder being much the same for all classes. The graded sites, which are responsible for about half the total deaths (in males, for whom alone the requisite occupational information is available), includes the upper alimentary canal from mouth to stomach inclusive, the skin and the larynx. It would therefore appear that cancer of these sites is largely preventable, though the factors determining its differential incidence will have first to be recognised.

Institute of Metals, Mar. 7 (Annual General Meeting).—**W. Rosenhain** (Presidential Address). It has been found by study of the microstructure of alloys that there is a close correlation between microstructure and all or most of the physical properties. The microstructure is the direct result of the mode of solidification of the alloy; and the most valuable diagram or chart which can be prepared for a series of alloys, therefore, is a chart showing the way in which they solidify and the changes which they undergo, in regard to structure, upon cooling after solidification. As an example of the need of great accuracy and completeness in the study of these diagrams, an account was given of the method of determining the 'solid solubility lines' of various alloy systems. Such determinations have not only furnished the explanation of the age-hardening of duralumin and other aluminium alloys, but form the foundation for a series of new and important alloys of copper and other metals. In some of these, notably the alloys of copper and beryllium recently developed in Germany, the age-hardening effects are very large. An alloy containing only a small percentage of beryllium in copper can have its Brinell hardness raised from 80 to 410 by age-hardening, the tensile strength in the latter condition being of the order of 90 tons per sq. inch. The production of high-strength copper alloys may prove to be of vital importance to the future of the non-ferrous industries.—**S. Beckinsale** and **H. Waterhouse**: the deterioration of lead cable sheathing by cracking and its prevention. The cause and prevention of the intercrystalline failures sometimes found in lead cable sheathing are discussed. The situations in which cable sheathing has failed by cracking indicate that the defect is a fatigue type of failure produced by small alternating stresses. The addition of other metals to lead raises the fatigue limit and so increases its resistance to this type of failure. Amongst the alloys which have been found very effective are certain ternary alloys containing cadmium.—**Ezer Griffiths** and **F. H. Schofield**: The thermal and electrical conductivity of some aluminium alloys and bronzes. Two groups of alloys were investigated: (1) Those rich in aluminium, with nickel, magnesium, iron, zinc, manganese, or silver as second or third constituents; (2) those rich in copper, with tin, zinc, lead, manganese, or aluminium. The aluminium alloys have a thermal conductivity of roughly 70 to 80 per cent. that of pure aluminium, whilst the bronzes range from one-fifth to one-tenth of the value for copper. In contrast with the pure metals, all give considerable increase of thermal conductivity with temperature. A minute amount of phosphorus in a bronze produces a marked lowering of the thermal conductivity. The lowering of the conductivity of copper due to an admixture of 10 per cent. of aluminium is comparable with that due to the same amount of tin. Of the aluminium alloys tested, the 8 per cent. copper and the 4·5 per cent. copper showed the highest conductivity (82 per cent. of that of pure aluminium). The lowest thermal conductivity of the series was given by a 13 per cent. zinc, 3 per cent. copper alloy (conductivity = 64 per cent. aluminium). The ratio of the thermal to the electrical conductivity in the range 80° to 300° C. obeys Lorenz's law with one or two exceptions.—**R. Chadwick**: The constitution of the alloys of magnesium and zinc. The metals form two intermetallic compounds, $MgZn_2$, $MgZn_5$, and all four solid phases; Mg, $MgZn_2$, $MgZn_5$, and Zn, form solid solutions. In analysing the alloys, the magnesium and zinc are precipitated separately as pyrophosphates from the solution of mixed chlorides. —**Hugh O'Neill**: Historical note on density changes caused by the cold-working of metals. Priority for the observation that its density decreases when a metal is cold-worked is generally attributed to certain continental workers, notably to Spring (1891). It appears that Berzelius (1844) may previously have noticed the effect, but it is certain that Charles O'Neill of Manchester published a careful research upon the subject thirty years before the work of Spring was printed.—**F. S. Grimston**: Season-cracking of small-arms cartridge cases during manufacture. Until recently, burst cases have been attributed to inferior metal, but the defect can be reproduced by certain combinations of the tools used in the drawing operations. Season-cracking in the walls of the case take place during the interval between a drawing operation and the subsequent annealing under certain conditions. The conditions are: (*a*) The existence of differential stresses in the case wall caused by tools of wrong design; (*b*) storage of the unannealed cases in contact with soapsuds contaminated with dilute sulphuric acid used in the cleaning processes.—**F. Hargreaves**: The ball hardness and the cold-working of soft metals and eutectics. For soft metals and eutectics, the relation between diameter of impression and duration of loading is given by the equation $d = ct^s$, where d = diameter of impression, t = duration of loading, and s and c are variable factors. The temperature of testing is of great importance. In all the cases examined the effect of work is to increase factor s, and it is suggested that in the case of pure metals it is a measure of the rate of spontaneous annealing.—**W. L. Kent**: The behaviour of metals and alloys during hot-forging. Small cylindrical specimens of pure metals and some brasses were forged with a standard blow of 50 ft.-lb. at temperatures up to the melting-points, and the mechanism of hot-forging investigated by measurements of the degrees of compression produced and by comparison of the Brinell hardness values so obtained. It is concluded that although the forging test does not measure the malleability of a metal or alloy, it will indicate the relative forgeability at different temperatures, and also the liability for cracking to occur during the operation. When a metal is worked at elevated temperatures, it strain-hardens in much the same way as at normal temperatures, but not to the same extent.—**W. A. Cowan**: Minute shrinkage cavities in some cast alloys of heterogeneous structure. Minute cavities in certain heterogeneous alloys are due to shrinkage, accompanying change in volume between liquid and solid phases, of a relatively low freezing-point component, where it last freezes after the bulk of the alloy has solidified at higher temperature. For example, some tin-base alloys, the main component of which is a solid solution of antimony in tin, which solidifies at 237° C., contain a small amount of the eutectic mixture with lead; this solidifies at 183° C., producing minute shrinkage cavities. Similar alloys without any lead content show no cavities.

(*To be continued.*)

MANCHESTER.

Literary and Philosophical Society, Jan. 10.—**B. B. Bancroft**: On the notational representation of the rib-system in Orthacea. A notation is described and applied to certain species and genera of Orthacea, which are very important fossils in the Palæozoic rocks. It depends upon the type of rib branching, and has been defined principally with reference to the dorsal valve. Certain longer ribs are determined as primaries; branches of primaries are termed secondaries, and branches of secondaries are termed tertiary ribs. The valve is bilaterally symmetrical, so that the ribbing can be described by reference to one half of the valve only. All ribs lying between their parent ribs and the median line are termed internals, and ribs lying on the outer sides of their parents are described as externals. These are represented by appropriate signs. The tertiary ribs derived from the fourth primary in a particular shell would be described thus:

$$4\bar{a}\bar{1},\ 4\bar{a}\bar{2},\ 4\bar{a}\dot{1},\ 4\dot{a}\bar{1},\ 4\dot{a}\dot{1}.$$

For descriptive purposes a rib and the entire system of branches derived from it is called a sector, which may be of primary, secondary, tertiary, or higher order, and is denoted by a Roman numeral or letter. The method lends itself to statistical and graphical representation.

PARIS.

Academy of Sciences, Feb. 6.—The president announced the death of H. A. Lorentz, foreign associate. —**Gabriel Bertrand** and **L. Silberstein**: The ordinary presence of barium, and probably of strontium, in arable earth. Twenty specimens of earth from France, Italy, Denmark, and Serbia have been proved to contain traces of barium. In certain cases spectroscopic proof of strontium was also obtained.—**E. Bataillon** and **Tchou Su**: Maturation, fertilisation, and polyspermia in the egg of *Bombyx mori*.—**G. Nicoladzé**: Contact between geometrical figures belonging to a continuous system.—**Jacques Chokhate**: The convergence of mechanical quadratures in an infinite interval. Applications to the problem of moments, and to the calculus of probabilities.—**Tibor Radó**: Remarks on subharmonic functions.—**J. A. Lappo-Danilevski**: Algorithmic resolution of the problem of Poincaré for systems of linear differential equations with arbitrary rational coefficients.—**Michel Plancherel**: The rôle of Laplace's transformation in the integration of a class of mixed problems of the hyperbolic type, and the developments in series of a couple of arbitrary functions.—**A. Kovanko**: A generalisation of nearly periodic functions.—**Nikola Obrechkoff**: The summation of certain divergent series. —**Bernard Salomon**: The gyroscopic analogies of electricity: asynchronous gyroscopic apparatus and the application of the theory of the gyroscope to continuous movement or to alternating movement. —**Kivelìovitch**: The problem of three bodies with successive collisions of one body with the other two. —**Julien Pacotte**: The electrical vector-potential with five components.—**A. Andant** and **E. Rousseau**: The photolytic action on pure saccharose of the total or filtered radiations of the mercury arc. Various light filters were employed, removing different parts of the spectrum: the amount of reducing sugar formed was taken as a measure of the photolytic action.—**Svend Aage Schou** and **René Wurmser**: The reducing power of glucose. The spectrographic study of glucose solutions, maintained out of contact with oxygen, affords evidence of the production of a reactive form which may account for the reducing power of these solutions. —**Jean Calvet**: The action of hydrochloric acid upon extra-pure aluminium. The resistance of highly purified aluminium to attack by dilute hydrochloric acid is only temporary, since after immersion for a period of some days the metal is clearly attacked, the hydrogen produced growing regularly for some time, and then becoming constant.—**Ch. Courtot**, **Fayet**, and **Parant**: Contribution to the study of the indene halohydrins.—**L. Bert**: The synthesis of benzene hydrocarbons by means of mixed organomagnesium compounds The decomposition by water of 25 mixed organomagnesium compounds, 21 of which have been prepared for the first time, constitutes a method of preparing benzene hydrocarbons which combines the advantages of the method of Friedel and Crafts and that of Fittig and Tollens.—**Marcel Godchot** and **Mlle. Cauquil**: Molecular transposition in the cycloheptane series. A reaction is described which transforms a seven carbon ring into a six carbon ring.—**Wahl** and **Féricean**: New derivatives of isoindigotin.—**Henri Moureu**: The tautomerism of the α-diketones. The two forms of methylbenzylglyoxal and their reciprocal transformation.—**L. Malaprade**: The oxidation of some polyhydric alcohols by periodic acid. Applications. Glycol, glycerol, erythrite, and mannite reduce periodic acid to iodic acid at the ordinary temperature, and a method of determining these alcohols is given which is based on this reaction.—**Joseph Péneau**: The presence of facies with schist structure in the Devonian of the region of Chalonnes (Maine-et-Loire).—**Pierre Pruvost**: The geological results obtained from the test boring of Ferrières-en-Bray.—**A. Demay**: The lower elements of the Cévenol tectonic complex.—**Etienne Patte**: The persistence of the genus Lingullela in the Tonkin Devonian.—**E. Chemin**: An endozoic Achrochætium and the development of its spores.—**Luigi de Caro**: The comparative energy yields of various glucides in the development of moulds. In the growth of moulds the ketonic grouping is better utilised than the aldehyde function.—**P. Bourcet** and **G. Dugue**: The digitin of Nativelle. A specimen of digitin prepared by Nativelle has been found to contain two substances, one soluble in chloroform and melting at 278° C., the other insoluble in this solvent, melting point 315° C. The latter is identical with digitonin; the former agrees with the gitogenin of Windaus and Schneckenburger.—**Raymond-Hamet**: The bradycardia produced by uzara and by other digitalis preparations.—**Philippe Fabre**: Direct muscular stimulation by progressive currents.—**G. Lavier**: Paravacuolar formations of the trypanosomes.

Harwood: The Age and Composition of the Whin Sill and the Related Dikes of the North of England.—A. W. Groves: The Identification of Dumortierite in Grains; Dumortierite in Cornish Granite.—Dr. T. V. H. Rao: On Bauxite from Kashmir, India.

Zoological Society of London, at 5.30.—Secretary: Report on the Additions to the Society's Menagerie during the month of February 1928.—G. C. Robson: On the Giant Octopus of New Zealand.—Dr. H. H. Scott: Tuberculosis in Marsupials.—Dr. H. C. James: On the Post-Embryonic Development of the Female Genitalia and of other Structures in the Chalcidoid Insect *Harmolita graminicola* Gir.—Dorothy J. Jackson: The Biology of *Dinocampus* (*Perilitus*) *rutilus* Nees, a Braconid Parasite of *Sitona lineata* Linn.—Dr. Marie V. Lebour: The Larval Stages of the Plymouth Brachyura.

Institution of Civil Engineers, at 6.

London Natural History Society (at Winchester House, E.C.), at 6.30.—Mrs. H. D. Kay: Sand Dunes.

Institution of Electrical Engineers (East Midland Sub-Centre) (at Technical College, Derby), at 6.45.—G. G. Blake: Applications of Electricity to Medical Practice.

Institution of Electrical Engineers (North Midland Centre) (at Hotel Metropole, Leeds), at 7.—A. H. Law and J. P. Chittenden: Higher Steam Pressures and their Application to the Steam Turbine.

Institution of Electrical Engineers (North-Western Centre) (at Engineers' Club, Manchester), at 7.—F. H. Rosencrants: Practice and Progress in Combustion of Coal as applied to Steam Generation.

Institute of Metals (Birmingham Local Section) (jointly with Birmingham Metallurgical Society and Staffordshire Iron and Steel Institute) (at Engineers' Club, Birmingham), at 7.—W. E. Ballard: Non-Ferrous Tubes.

Royal Photographic Society of Great Britain (Scientific and Technical Group) (Annual General Meeting), at 7.—W. T. Astbury: Photography and Photometry in X-ray Crystal Analysis.

Institution of Engineers and Shipbuilders in Scotland (at 39 Elmbank Crescent, Glasgow), at 7.30.—Ing. Giovanni Chiesa and D. M. Shannon: The Development of the Fiat Marine Oil Engine.

Royal Society of Medicine (Pathology Section), at 8.30.—Annual General Meeting.

WEDNESDAY, March 21.

Society of Glass Technology (in Coal, Gas, and Fuel Industries Department, University, Leeds), at 2.30.—J. T. Howarth and Prof. W. E. S. Turner: The Study of a Fundamental Reaction in Glass Making.—E. J. C. Bowmaker: A Method of Testing the Probable Durability of Tank Blocks.

Electrical Association for Women (at Westminster Electric Supply Corporation, 112 Victoria Street, S.W.1), at 3.—The History of Electricity Supply in the Westminster District (Lecture).

Geological Society of London, at 5.30.—Dr. F. B. A. Welch: The Geological Structure of the Central Mendips.

Newcomen Society for the Study of the History of Engineering and Technology (in Prince Henry's Room, 17 Fleet Street), at 5.30.—J. E. Hodgson: James Sadler: Aeronaut, Engineer, Chemist, and Inventor.

Institution of Electrical Engineers (jointly with Kindred Societies) (in Mappin Hall, Sheffield University), at 7.30.

Merseyside Aquarium Society (at 1 Falkland Road, Egremont), at 7.30.—A. Wilkinson and J. Gould: Display of Pond-Life, etc., under the Microscope, and Short Lantern Lecture by A. Wilkinson.

Royal Meteorological Society, at 7.30.—H. W. Newton: The Sun's Cycle of Activity (G. J. Symons Memorial Lecture).

Royal Microscopical Society, at 7.30.—Prof. D. C. Blair: A Nerve Mechanism in the Capillaries of Muscle.—Dr. J. A. Murray: Contribution to the Study of Diatom Markings.—Dr. G. S. Sansom: A Portable Microscope Table.

Royal Society of Arts, at 8.—Lieut.-Comdr. R. T. Gould: The Modern Typewriter and its Portable Future Development.

Folk-Lore Society (at University College), at 8.—Exhibits and Short Communications.

Institute of Chemistry (London Section).

Electroplaters' and Depositors' Technical Society (jointly with Institute of Chemistry—London Section).—D. J. Macnaughtan: Common Defects in Nickel Deposits.

Institution of Mechanical Engineers (Bristol Branch).—E. G. Herbert: Cutting Temperatures: their Effects on Tools and on Materials subjected to Work.

THURSDAY, March 22.

Chemical Society (Annual General Meeting), at 4.—Prof. H. B. Baker: Constitution of Liquids: Some New Experiments (Presidential Address).

Royal College of Physicians of London, at 5.—Dr. J. Collier: Epilepsy (Lumleian Lectures) (I.).

Royal Institution of Great Britain, at 5.15.—Group-Capt. Martin Flack: Physiological Aspects of Flying.

Institution of Electrical Engineers, at 6.—P. D. Morgan: Electrical Research Association Report on a Critical Study of the Continuous Rating of Low-Pressure Ordinary-Duty Fusible Cut-Outs.

Institute of Chemistry (Edinburgh and East of Scotland Section) and Society of Chemical Industry (Edinburgh and East of Scotland Section) (at 36 York Place, Edinburgh), at 8.—Dr. W. T. H. Williamson: Recent Advances in the Chemistry of Soils.

Royal Society of Medicine (Urology Section), at 8.30.—F. Kidd and others: Discussion on The Treatment of Stricture by Excision.

Institution of Mechanical Engineers (Manchester Branch).—Capt. H. G. M. Beames: The Reorganisation of Crewe Locomotive Works.

Institution of the Rubber Industry (Manchester Section).—B. D. Porritt: Single Texture Proofing.—Dr. E. P. Rydings: Paper.

FRIDAY, March 23.

Physical Society (at Imperial College of Science), at 5.—W. D. Flower: The Terminal Velocity of Drops.—Satyandra Ray: Longitudinal Waves Along a Rod.—J. J. Manley: The Damping of Mercury Ripples.—Demonstration by J. E. Calthrop of *Die Kaskadenmethode*.

Royal College of Surgeons of England, at 5.—Sir Arthur Keith: Demonstration of the Present State of Knowledge regarding the Innervation and Movements of the Intestine.

British Psychological Society (Æsthetics Section) (at Bedford College, Regent's Park, N.W.1), at 5.30.—Miss A. M. Bodkin: The Study of Imagination through Poetry.

Society of Chemical Industry (Glasgow Section) (at 39 Elmbank Crescent, Glasgow), at 7.—Annual Business Meeting.

Institution of Electrical Engineers (London Students' Section), at 7.—G. P. Barnard: The Vacuum Tube Family.

Manchester Literary and Philosophical Society (Chemical Section), at 7.

Institution of Mechanical Engineers (Informal Meeting), at 7.—J. H. Walker and others: Mechanical Handling of Goods.

North-East Coast Institution of Engineers and Shipbuilders (Informal Meeting) (at Newcastle-upon-Tyne), at 7.15.—H. G. Williams: The Steering of Ships.

Junior Institution of Engineers (Informal Meeting), at 7.30.—B. J. Axten: High Tension and Low Tension Supply for Wireless Receivers from Electric Mains.

Society of Chemical Industry (Chemical Engineering Group) (at Chemical Society), at 8.—A. A. King: Ultra-Violet Radiation in Industry.

Royal Society of Medicine (Epidemiology Section), at 8.—Dr. C. O. Stallybrass: Season and Disease.

Royal Institution of Great Britain, at 9.—Dr. E. Cohen: A Physical Chemist in Search of Purity in an Impure World.

Society of Dyers and Colourists (Scottish Section).—A. J. Hall: Some Features of the Swelling and Solution of Cellulose.

SATURDAY, March 24.

Royal Sanitary Institute (at Municipal Buildings, Taunton), at 10.30 A.M.—Discussion on Present Tendencies regarding Disinfection and on House Refuse Collection.

Royal Institution of Great Britain, at 3.—Sir Ernest Rutherford: The Transformation of Matter (III.)

PUBLIC LECTURES.

SATURDAY, March 17.

Horniman Museum (Forest Hill), at 3.30.—H. Harcourt: Food and Famines in India.

MONDAY, March 19.

Gresham College, at 6.—G. P. Bailey: Modern Science and Daily Life: The Conquest of the Air.

East Anglian Institute of Agriculture (Chelmsford), at 7.—A. Amos: High Farming v. Low Farming.

TUESDAY, March 20

Imperial College of Science—Royal College of Science, at 5.30.—Prof. K. M. G. Siegbahn: X-rays. (Succeeding Lectures on Mar. 21 and 22.)

WEDNESDAY, March 21.

British Medical Association (Tavistock Square, W.C.1), at 3.—Sir George Newman: The Fundamentals of Health (Sir Charles Hastings Memorial Lecture)

THURSDAY, March 22.

British Medical Association (Tavistock Square, W.C.1), at 5.30.—Dr. E. Graham Little: The Future of Medical Practice.

SATURDAY, March 24

Horniman Museum (Forest Hill), at 3.30.—Dr. E. Marion Delf: Light and Life.

CONFERENCE.

March 28 to 31.

German Balneological Congress (at Baden, near Vienna).

New Statutes for the University of London.

THE second draft of the proposed Statutes for the University of London has been published by the Commissioners appointed under the University of London Act, 1926. This Act directed that statutes for the University were to be made by the Commissioners "in general accordance with the recommendations" contained in the Report of the Departmental Committee appointed by the President of the Board of Education (Mr. Trevelyan) in 1924, "subject to any modifications which may appear to them to be expedient"; and the first draft implemented these recommendations, save in one or two particulars, for example, two women's colleges—the Royal Holloway College and Westfield College—were added to the list of colleges accorded direct representation on the Senate, thus ensuring further representation of the special interests of women; and the Principal of the University was made *ex officio* a member of the Senate.

Both before and after the publication of the first draft, voluminous representations were made to the Commissioners. One subject on which representations were made, of special interest to readers of NATURE, is the recognition of research as an important activity of the University. The new draft Statutes provide for the recognition of research institutes as 'Schools of the University' and divide the 'Schools' into three categories—(1) Incorporated Colleges, the title curiously given to the two colleges, University College and King's College, which have ceased to be 'incorporated' in the legal sense; (2) Colleges; (3) Research Institutes. The division of the existing 'Schools' has been carried out by the Commissioners in an amateurish way, for the category 'Colleges' as published includes some professional schools, and the category 'Research Institutes' includes institutions such as the School of Pharmacy and the School of Oriental Studies, the chief work of which is instruction rather than research.

The title of the body charged with the control of the finances of the University has been changed from 'Council'—a name possibly suggesting a body subordinate to a larger body—to 'Court,' a more appropriate title for a body created *ad hoc* with powers both independent and concurrent.

The most important change introduced by the second draft of the Statutes is the complete abrogation of the direct representation of colleges on the Senate. Objection was taken to the principle of college representation on the ground that a university is traditionally a self-governing guild, not a federation of colleges, and that the members of the supreme governing body in academic matters should not *represent* independent or *quasi*-independent institutions. Huxley gave his views on this question to the Gresham Commissioners in 1892 with his accustomed clearness. "Unify without fettering" expressed his ideal of the relation of university to college. He advised against giving the professoriate a preponderant representation on the Senate and said he would certainly object to any system "by which institutions whether called colleges or by any other names got the whip hand of the University." He would not "cumber" the Senate with representatives of the colleges—referring no doubt especially to lay representatives.

This view has been accepted, on re-consideration, by the present Commissioners. The alternative adopted is the appointment of the heads of the nine named colleges, together with two deans of medical schools to be selected, as official members of the Senate. Even those who objected on principle to college representation recognised that the heads of colleges, by reason of their wide knowledge and experience, were most eligible on personal grounds for membership of the Senate. Apparently it was not possible to avoid giving permanent seats to the heads of the selected colleges—a method which has disadvantages in a democratically constituted governing body—though in the case of the medical schools a system of selection has been adopted.

In addition to the Chairman of Convocation, who is a member *ex officio*, the representation on the Senate of the graduates in Convocation has been increased by one member (from 16 to 17), who is allocated to science; and similarly an additional representative has been accorded to the Faculty of Medicine, composed of teachers (an increase from two to three), the effect being to increase the number of Faculty representatives also from 16 to 17. Past controversies, as well as the relative importance of scientific and medical interests in the University, justify this change. The total membership of the Senate as re-constituted will be 52 (or possibly 53).

The appointment and dismissal of members of the financial and administrative staff of the University is, by a new draft Statute, to rest with the Senate, except as to the Principal, who is to be appointed by the Senate with the concurrence of the Court. This is a new and surprising provision, its effect apparently being to prevent the Court appointing its own officers for the discharge of its onerous duties in relation to finance, including the obtaining of benefactions and public grants for the University.

Another surprising innovation is the proposed acceptance, as internal students, of students who have not matriculated in the University, including students preparing for degrees of other universities (for example, medical students preparing for degrees at Oxford and Cambridge) and students preparing for the diplomas within the purview of the Academic Council. The definition of internal students is contained in the schedule to the Act of 1898, and the Departmental Committee recommended no change in this important matter. It is a wide departure from established practice to register internal students without any prescribed educational standard, though it must be remembered that Huxley was opposed to all matriculation tests, and there will be great advantages in enabling all regular students of colleges to register as internal students. The registration of external students, a much-needed reform, is authorised by a new draft Statute, but not directed.

On the difficult question of an 'appointed area' for the University, the Commissioners have not found enlightenment, retaining the illogical and unscientific London County Council area for the admission of new 'Schools,' except as regards institutions "wholly or mainly devoted to the pursuit of some branch of University study which cannot, in the opinion of the Senate, be adequately pursued within that area," for which no area is prescribed. The present thirty-mile radius for institutions at which teachers can be 'recognised' disappears, the recognition of teachers under the new conditions being without restriction of area. Is it to be inferred from these new arrangements that places like Wimbledon, Watford, Chingford, Chislehurst—admirably situated for day and residential colleges for London students—are outside the sphere of influence of the University of London and are at liberty to create new universities? Even at this late hour, it may be hoped that the Commissioners will find inspiration for a better definition of the 'London area' in respect of higher education.

The Commissioners announce April 30 as the last day for receiving further representations, and it is to be presumed that renewed controversy is not expected. In view of the important new issues raised by the amendments to the first draft of the Statutes, the time allowed for further discussion appears to be unduly restricted

Economic Ornithology.

The Practical Value of Birds. By Prof. Junius Henderson. Pp. xii + 342. (New York: The Macmillan Co., 1927.) 10*s*. 6*d*. net.

ALTHOUGH we in Great Britain are only just beginning to realise the importance of avian economics, other countries have long been cognisant of the important part played by wild birds, and none more so than the United States of America. Since 1885, when investigations were commenced under the ægis of the Government, there has been a long series of distinguished investigators whose work has been published in upwards of two hundred memoirs. Valuable as these works are to all engaged on similar researches in this particular branch of science, they are scarcely the literature desired or to be understood by a large body of the general public who are anxious to learn something of the economic status of the wild bird fauna. It is therefore most fitting that the results of these invaluable suggestions should be summarised, and a résumé provided for those generally interested, for such cannot fail to bring home to a wide circle of readers the extent and national value of this long and brilliant series of investigations.

Prof. Henderson's work is divided into two parts, the first dealing all too briefly with the principles involved and the more important groups of facts. The seventeen chapters are contained in about one hundred pages, and, while full of interest, scarcely do justice to the voluminous literature on the subject. The second part consists of a systematic discussion of "the more significant data" relating to American economic ornithology. The author has not only included a very full bibliography, but also, unlike many present-day authors, has credited every author quoted with an actual reference.

The work that has emanated from the Bureau of Biological Survey is so thorough and reaches such a high standard that we wish the author had confined himself to an epitome of this alone. We question whether the results obtained by Aughey fifty years ago have more than historical value. As all investigators know, odd notes on the food of one or two specimens of a bird observed at a particular season and district are really of very little value, and in the present case they only tend to detract from the valuable results obtained by workers of long experience. Any further advancement in the subject of the economic status of any species of wild bird will only be made as the result of a systematic examination of the stomach contents of a large series of specimens obtained during each month of the year and from various districts. This is clearly indicated by the work of Barrows, Beal, Fisher, Judd, Kalmbach, McAtee, Oberholser, Wetmore, and others, who have laid a sure and lasting foundation for economic ornithologists.

Useful as are the details given under the various species as to the volumetric percentages of the different food items, in our opinion they are insufficient for the general reader and others for whom this book is intended. As McAtee has so pertinently remarked, such figures are merely "convenient handles to facts" and require interpreting. Significant as they are to one versed in the study of animal economics, they convey very little information to others. The reader is left to decide for himself whether a species is beneficial, injurious, or neutral in its relationship to mankind. It is to be regretted that the author has not summarised the economic status of either individual species or the family as a whole. This is such a prominent feature in the works of Beal and other writers that we are rather surprised at the omission, for it is obvious that the general reader wishes to learn the conclusions arrived at after the prosecution and completion of a long, highly technical, and extremely difficult investigation.

As American workers have since 1885 employed the volumetric system of expressing the volume of food contained in a bird's stomach, we should have expected a more precise method of stating the quantities of food required by birds; unfortunately such is here absent. If a bird requires the cubic capacity of its stomach filling four or five times a day, it is surely important to know what that cubic capacity means in grains and ounces, when such information is obtainable, in order that the volumetric analyses of individual stomachs or the total averages of such may be rightly understood. We are fully aware that, unfortunately, such figures do not exist for all species, desirable as they are, but Beal gives these for many species, and other writers have estimated the weight of the total bulk of food required in a year.

One fact which is brought out by these researches is that of upwards of five hundred species of birds, the stomach contents of which have been examined, very few indeed are proved to be wholly injurious. Species that are injurious in one part of the country during a season are just as beneficial, or even more so, in another district during a later season, all of which only tends to show how very exhaustive an inquiry should be before any species is condemned.

If we seem to have dwelt upon the shortcomings of this work, it is not because we do not appreciate its good points, which are many and obvious. Should a further edition be called for, we trust the above criticism will be considered helpful. Although confined almost entirely to American birds and the work of American workers, the general principles enunciated hold good for practically all countries, and all interested in the economics of wild birds will find a wealth of material for careful consideration. Prof. Henderson's book is a valuable addition to the literature on economic ornithology, and he is to be congratulated on meeting an obvious need.

WALTER E. COLLINGE.

Science and Faith.

Adventure: the Faith of Science and the Science of Faith. By the Rev. Canon Burnett H. Streeter, Catherine M. Chilcott, John MacMurray, and Dr. Alexander S. Russell. Pp. ix+247. (London: Macmillan and Co., Ltd., 1927.) 7*s*. 6*d*. net.

THE book, Canon Streeter tells us, arose out of a series of informal conferences at which the relations between science and religion were discussed, mainly by the "scientists and philosophers of the post-War generation in Oxford." The essays have, therefore, somewhat of a common viewpoint, and it is a novel and stimulating one. The title is intriguing. We do not as a rule associate the idea of adventure with religion, or very often with science, and books about their relation are apt to be dull and platitudinous. The present volume does escape that reproach, and does treat the question from a new viewpoint.

Dr. A. S. Russell, who writes the first paper, on "The Dynamic of Science," has little difficulty in showing that the spirit of adventure is active in science at the present day, particularly in the physical sciences.

"At the present day," he says, "the student of natural science does not allow himself to be deterred from a theory merely because it appears incredible or incompatible with all that has gone before. To such theories indeed he is attracted. The spirit of adventure is strong in him. During the second half of last century the development of science was away from adventure and towards a form of intellectual pharisaism. All the great principles appeared to have been discovered and correctly formulated, and the scientist was inclined to believe that all that needed to be done, especially in physics, was to improve the petty details. This point of view changed rapidly when it was realised that the details were not petty, but capable of leading to astounding conclusions" (p. 18).

It is the facts themselves that have shaken the old conceptions—the facts discovered by bold and patient experiment. Nature is much more remarkable than our theories or imaginings admit. Dr. Russell writes mainly from the point of view of the physicist, and we miss in the book any equivalent treatment of biology. Or is the spirit of adventure, of revolution, less manifest in this domain?

What of adventure in religion? Mr. MacMurray considers this in a really remarkable essay entitled "Beyond Knowledge," in which he deals in a penetrating way with the relation of 'faith' to 'knowledge.' He rejects the common view that faith is a kind of knowledge—that it is belief opposed to reason, or based upon intuition, or on mystical experience. He considers it to be an attitude of will, a way of acting in the face of uncertainty or ignorance. This is, he maintains, what faith means in the New Testament, and he discovers the same attitude at the root of scientific endeavour.

"Modern science," he writes, "rests upon an attitude of will which meets the impotence of mere thought by a continuous reconstruction through criticism and experiment. This attitude of will, we have argued, is the presupposition of all living knowledge, and we have suggested its identity with faith" (p. 37).

It is action—the experimental and courageous grappling with practical difficulties—that is "beyond knowledge." Purely rational and "careful" thought does not take us very far; there must be constant testing by experiment, constant adventuring into the yet unknown complexities of Nature. Science and religion are both based upon this attitude of faith, and "Such a life of faith lies beyond knowledge, because it is the transcendent spirit of knowledge, the courageous life of creative adventure" (p. 45).

It is perhaps rather unfair to Mr. MacMurray to attempt to present his point of view in a few sentences. The whole essay, which is closely reasoned and rich in suggestion, must be read. There is much in it open to criticism, but it does present a vital and stimulating point of view,—all the more stimulating if one does not fully agree with it.

The remaining essays in the book take us rather beyond the scope of subjects appropriate for discussion in NATURE. There are three theological essays by Canon Streeter, Mr. MacMurray, and Miss Chilcott, and a long article on "Moral Adventure" by Canon Streeter, in which the problems of sex morality are dealt with in a broad and sane, but not very adventurous, way.

E. S. R.

Pascal as a Man.

Portrait of Pascal. By Mary Duclaux (A. Mary F. Robinson). Pp. 232. (London: T. Fisher Unwin, Ltd. (Ernest Benn, Ltd.), 1927.) 10*s.* 6*d.* net.

THIS new short life of Pascal—for we must call it that in spite of Mme. Duclaux—will take its place suitably beside the little books on Newton and Descartes which have been recently noticed in our columns. In some ways the Pascal book ranks above the others, because Pascal was so much more interesting as a man than either Newton or Descartes. He died younger, less than forty years of age, and he had all the fascination for his contemporaries of a dreamy delicate man, full of great thoughts and divided in his allegiance between his passion for physical experiments and mechanical inventions and religious solicitude for the welfare of his soul. It was the latter interest that finally prevailed, and—with all reverence be it said—it was not the higher interest, for the religion of Port Royal, which carried off first his sister Jacqueline and then himself from the parental moorings, was not of the highest or most inspiring order. It was morbid and introspective, and put the salvation of the individual sinner above all other thoughts, human or divine. That Pascal was equally open to the other side of religion and morals—the social and humane—is evident from the tenderness of his private life and many strains in his writings; but for eight years before he died the pietistic strain was uppermost. The root cause was physical. He had suffered from childhood from a paralytic nervous weakness, and this was aggravated by a carriage accident in 1654, from which he never really recovered.

It is the struggle and the contrast between the two sides of Pascal's nature which gives the penetrating charm to all his writings, and especially to the "Pensées." Something like Shelley in personal appearance, he was like him too in the conflict between the positive and the dreamy tendencies in his thinking, but whereas Shelley sets free his imagination in picturing and glorifying the powers and future of man, Pascal is oppressed by the thought of the infinite pettiness of the individual, face to face with the immensities of space and time. The seventeenth article of the "Pensées" gives the best expression to this feeling. It ends with the quietist doctrine, that being unable to comprehend the whole or pass beyond that middle point between nothing and the infinite, true wisdom is to be found in repose, each in the place where Nature has placed him.

As the man of science it is difficult to estimate Pascal's contribution with certainty, owing to the share taken by others in his most famous work. The first idea of the pressure of the air, which was suggested by Torricelli's tube, came no doubt from Galileo. Pascal plunged into the discussion with all the ardour of his scientific, inquisitive nature. It was he probably who first thought of the decisive experiment on the Puy-de-Dôme, though Descartes claimed the credit in a conversation with Pascal. Such questions are often insoluble, when some new question is being eagerly canvassed by a group of men in close contact with one another. We may be quite sure of one or two points in this much-discussed story. One is that Pascal, being the retiring and self-centred person, was likely to have thought much more about it than others who made more noise in the world, and that he was the indefatigable experimenter on any subject in which his interests were engaged. He made fifty models of the calculating machine which was to help his father in reckoning the taxes payable by the individuals in his district. Above all, it is certain that, had his life been prolonged and had he been free from the religious obsessions which secluded him for years, and took up most of his writing time, he would have done far more for the advance of physical science.

At twelve, Pascal had been found by his father making out for himself the thirty-second proposition of Euclid on the equality of the angles of a triangle to two right angles. At sixteen he had written a complete treatise on conic sections. Nothing but good health and concentration were needed to make him the greatest geometer of modern times, the 'New Archimedes,' as Father Mersenne called him. As it was, he remains a brilliant and tragic figure, the broken column in the history of science. Mme. Duclaux catches this aspect of him admirably in her book, but she should have found a prominent place for the inspiring thought which he develops at some length in the preface to the "Traité du vide": "Toute la suite des hommes, pendant le cours de tant de siècles, doit être considérée comme un seule homme qui subsiste toujours et qui apprend continuellement." This he points out is the distinguishing characteristic of human intelligence. The 'fragile science' of bees and ants does not grow greater with the generations. But man is born for infinity. It was the thought which, had he followed it throughout, would have given the grand consistent purpose to his life.

F. S. Marvin.

Discharge-tube Physics.

Handbuch der Experimentalphysik. Herausgegeben von W. Wien und F. Harms. Band 14: *Kathodenstrahlen*, von P. Lenard und A. Becker; *Kanalstrahlen*, von Wilhelm Wien. Pp. xiv + 788. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1927.) 72 gold marks.

In contemplating this massive volume of nearly eight hundred pages, one's thoughts irresistibly fly back to Sir J. J. Thomson's pioneer little book containing his Princeton lectures on "The Discharge of Electricity through Gases," which, published in 1898, was followed five years later by his monumental "Conduction of Electricity through Gases." This latter work not only collected and discussed in masterly fashion the relevant knowledge to date, but also by its suggestiveness served as an inspiration for the next generation of workers. There must be very many who have regretted that no recent revised edition has been forthcoming, though one realises how formidable the task would be to preserve the original degree of completeness in all the ramifications which the subject has since assumed.

Some of the developments are fraught with importance to the general community; others have contributed vitally to the more abstract aspects of scientific work. A few of these developments, which have resulted from or been influenced by investigations on gaseous ionisation, come to mind at once — thermionics and the hot-cathode valve, X-rays, cathode rays, positive rays, radio-activity, photo-electricity, electric lighting. The list might be greatly extended. In each of the subjects an enormous literature has come into being. Take, for example, the present volume on *Kathodenstrahlen* and *Kanalstrahlen*, terms, we may recall, which were introduced by Goldstein, the former in 1876, the latter in 1886. Prof. Lenard and Dr. Becker's treatment of cathode rays alone extends to above four hundred large and closely printed pages, while Prof. Wilhelm Wien's discussion of positive rays is no less impressive. These contributions bear testimony, were it needed, to the epochal stimulus to physics which followed Sir J. J. Thomson's isolation of the electron thirty years ago, and recall Maxwell's far-seeing prediction in the early 'seventies of the great potentialities of the discharge tube contrived by Hauksbee more than two centuries ago.

As would be anticipated from the standing of its authors, the book under review is characteristically complete, authoritative, and exact, and, so far as we have been able to test it, fair in its recognition of work carried out in other countries. There are more than 100 tables and nearly 500 figures. The volume is indeed a mine of information and remarkably up-to-date despite its size. In so comprehensive a work we find it difficult within the compass of a short review to single out any particular aspect for comment, but the treatments of their own investigations by Prof. Lenard and Prof. Wien respectively have a conspicuous interest and freshness of outlook. The latter's generous recognition of the work of Sir J. J. Thomson and Aston on positive rays calls for particular notice.

We confess we see little or no advantage in the plan of combining what are two independent treatises in one volume. Even now they are separately indexed, and the paragraphs, figures, and tables in the two sections are separately numbered. If each section had been issued independently, we venture to think it would have been in the interests of both the public and publisher. As it is, the volume, in view of its costliness, will mainly find a home on the shelves of institutional libraries. The publishers deserve commendation for the excellence of the printing, binding, and general 'get-up.'

G. W. C. K.

Our Bookshelf.

(1) *Das elektromagnetische Feld: ein Lehrbuch.* Von Prof. Emil Cohn. Zweite völlig neubearbeitete Auflage. Pp. vi + 366. (Berlin: Julius Springer, 1927.) 24 gold marks.

(2) *Quelques idées sur l'électrodynamique: théories nouvelles sur l'oscillateur de Planck et le mouvement autonome exposées devant la Société française de Physique.* Par R. Ferrier. Pp. 48. (Paris: Albert Blanchard, 1927.) 5 francs.

(1) This book is a second edition of the author's work of the same title published in 1900. It is much smaller in size than the first edition, but the arrangement of the subject matter is more carefully balanced, and the thread of the general argument is not now broken by frequent incursions into the realm of the practical realities of the subject. The whole treatment—as in the first edition—is based on the Hertzian view of an electric field which recognises matter only indirectly by its influence on the electric and magnetic properties of the ether. This view would never have persisted in face of the much greater simplicity of the modern electrical theory of matter, were it not that certain of the general critical results deduced in it seem to be supported by certain results in the more modern development, which are nevertheless, in spite of their persistence, erroneous. We refer in particular to the expressions for the energies and tractions in the field. Never-

theless, this book can still be recommended to those who wish to become acquainted with every side of a subject which has perhaps not yet reached its ultimate form.

(2) An ingenious illustration pointing the last remark of the previous notice is provided by R. Ferrier's little pamphlet. By a slight and apparently insignificant mathematical modification of the fundamental equations of Maxwell's theory—supported, however, by very cogent physical argument—certain extraordinary possibilities are opened out, which the author very ingeniously connects up with the question of the structure of the ether and the origin of the discontinuities of the quantum theory. New types of radiation fields—associated with such an old friend as the Hertz-Planck oscillator—are exhibited and their physical significance indicated. The ideas are of course merely tentative and very highly speculative, but they serve to illustrate the alternative possibilities of a theory, one half of the theoretical development of which is probably still nothing but pure conjecture. G. H. L.

Collected Physical Papers. By Sir Jagadis Chunder Bose. (*Bose Institute Transactions*, 1927.) Pp. xii + 404. (London: Longmans, Green and Co., Ltd., 1927.) 10*s.* net.

Sir Jagadis Bose has brought together in this volume a number of papers, mainly on physical subjects, written between 1895 and 1925. They include some of his papers on the applications of physical methods to the study of living matter. Of recent years he has devoted himself mainly to this branch of the subject. His early researches were on the optical properties of electric waves. They were made soon after Hertz's experiments, and his success was largely due to the method he perfected of generating electric waves, the wavelengths of which were within a few octaves of the waves forming visible light. Sir Jagadis obtained important results in this field on such subjects as coherence, polarisation, double refraction, and rotation of the plane of polarisation.

When working with receivers for electric waves, the author found that the sensitiveness of metallic detectors disappeared when they were subjected to continuous stimulation. When, however, they were allowed to rest for a sufficient period, they regained their normal sensitiveness. The records he obtained of the successive responses of metallic detectors were very similar to those he obtained when experimenting on the fatigue of an animal muscle. Thinking that prolonged rest would make a metallic detector more sensitive, he laid it aside for several days. On again testing it, he was surprised to find that it had become inert. A strong electric shock, however, made it sensitive again. He concludes that this experiment indicates two opposite treatments for fatigue from overwork and for inertness due to long passivity. No break was found in the continuity of the phenomena.

Sir Jagadis Bose considers that there is no line of demarcation between the physical phenomena and the physiological phenomena. It is impossible to say whether a phenomenon is one shown by dead matter or a vital phenomenon peculiar to the living. The book contains brief accounts of many interesting and suggestive experiments.

Operational Methods in Mathematical Physics. By Dr. Harold Jeffreys. (Cambridge Tracts in Mathematics and Mathematical Physics, No. 23.) Pp. vii + 101. (Cambridge: At the University Press, 1927.) 6*s.* 6*d.* net.

The operational methods of Heaviside for the solution of differential equations have the advantage of proceeding direct to the result in terms of given boundary conditions. Bromwich's interpretation of the operators by means of contour integrals have led to a generality and convenience of application which will ensure a warm welcome from mathematical physicists of Dr. Jeffreys' lucid and interesting exposition. Moreover, this is the only available connected account of Heaviside's methods, and is illustrated by a variety of applications. The value of the book is enhanced by the inclusion of a chapter on dispersion, with a description of the method of 'steepest descents.'

Éléments de géométrie infinitésimale. Par Prof. Gaston Julia. Pp. vi + 242. (Paris: Gauthier-Villars et Cie, 1927.) 45 francs.

This is an interesting course on differential geometry of three dimensions, which occupies an intermediate place between Darboux's "Théorie des surfaces" and such accounts of the subject as are to be found in most treatises on analysis, Goursat, for example. The emphasis is rather on the analytical than on the geometrical side, and a good deal of attention is given to the theory of contact and envelopes. The theory of congruences of lines is developed in some detail and, in particular, there is a discussion of singular lines as affording an application of singular integrals of differential equations.

The Romance of Chemistry. By Prof. William Foster. Pp. xvi + 468 + 31 plates. (London: George Allen and Unwin, Ltd., 1927.) 12*s.* net.

Prof. Foster's book is clearly written and gives an interesting account of many parts of chemistry and of its border-line subjects which should appeal to the general reader. Many of the examples chosen will, no doubt, be more familiar to American than to European readers, but the book can be recommended as a very good popular account of some of the generally interesting parts of modern chemistry.

Vorlesungen über Differential- und Integralrechnung. Von Prof. R. Courant. Band 1: ***Funktionen einer Veränderlichen.*** Pp. xiv + 410. (Berlin: Julius Springer, 1927.) 18·60 gold marks.

This is simply an ordinary text-book of calculus, without any freakish ideas and without undue elaboration of any special point leading to lack of balance. The volume does not, however, contain anything of importance not accessible in current English mathematical literature.

Letters to the Editor.

The Activation of Cholesterol at Liquid Oxygen Temperature.[1]

AT the temperature of liquid oxygen (– 183°), most bimolecular chemical reactions are largely inhibited. The rates of these reactions, in general, decrease rapidly with decreasing temperature. At very low temperatures the rates become too small to be measured, and for practical purposes it may be said that reaction ceases. This is especially true of oxidations, since, for example, neither sodium nor phosphorus immersed in liquid oxygen undergoes any apparent oxidation. However, the rates at which photo-molecular changes take place decrease more slowly with temperature. With this in mind, the irradiation of activatable cholesterol was carried out in liquid oxygen with the object of obtaining evidence as to the nature of the change involved. It was found that cholesterol of ordinary purity even at liquid oxygen temperature becomes antirickctic upon exposure to ultra-violet light.

The cholesterol used in these experiments melted clear at 149°. An investigation of its absorption spectrum by Dr. W. A. MacNair demonstrated that it contained 1·2 parts per thousand of ergosterol. Preliminary biological tests proved it to be highly activatable, although not antirickctic prior to irradiation. Our biological technique (line test) is described elsewhere.[2]

Irradiation was performed as follows: A cylindrical brass tube 42·5 cm. long and 4·5 cm. in diameter, closed at the lower end, was immersed in liquid oxygen contained in a silvered Dewar flask. The depth of immersion varied between 25 cm. and 15 cm. on account of evaporation of the oxygen. To prevent the condensation of water vapour in the tube and the settling of frost on the sample to be irradiated, the open, upper end of the tube was covered with a quartz plate thermally insulated from the metal by a ring made from asbestos board. A thin disc 4·2 cm. in diameter bearing 200 mgm. of pulverised cholesterol was lowered to rest on the bottom of the tube, and allowed to cool to liquid oxygen temperature. A quartz mercury vapour arc was adjusted a few centimetres above the tube and operated at 120 volts with about 30 ohms resistance in series. After irradiation for 105 minutes, the cholesterol was allowed to warm to room temperature, then dissolved in ether and evaporated on to McCollum's Diet 3143. Before and after irradiation the cholesterol was carefully protected from ultra-violet light. A similar experiment was made with the same apparatus, but at room temperature. On account of transportation, etc., a week elapsed between the preparation and administration of the modified diets.

The cholesterol irradiated at room temperature induced advanced healing of rickets when administered at 1/10 per cent., or even at 1/100 per cent. in the diet. The cholesterol irradiated at liquid oxygen temperature induced advanced healing at 1/10 per cent., but failed at 1/100 per cent. Thus it is evident that cholesterol is readily activated at liquid oxygen temperature, although the product obtained under the conditions of this experiment was not so potent as the product of irradiation at room temperature.

We regard these data as a strong confirmation of the evidence which has been accumulated recently by Rosenheim and Webster,[3] Windaus and Hess,[4] and Bills and McDonald,[5] that the activation of cholesterol (or ergosterol) consists not in an oxidation, but in an isomerisation—a rearrangement at the double bond or an *Elektronenverlagerung*.

In the activation of sterols by ultra-violet rays, it is important to consider the temperature coefficients of both the vitamin formation and accompanying destruction. For the formation the coefficient is evidently low. We find, however, that the spontaneous deterioration of (unactivated) ergosterol has a high temperature coefficient. If activated ergosterol also exhibits a high coefficient in its decomposition, then the way is clear for the preparation of a vitamin D of greater potency than has hitherto been attained.

Cholesterol and Vitamin D.

BILLS, Honeywell and MacNair have recently demonstrated (*Jour. Biol. Chem.*, 76, 251; 1928) that both ergosterol and ordinary purified cholesterol, in addition to the previously observed well-defined absorption bands at 293·5, 281·5, and 270 $\mu\mu$ (Morton, Heilbron and Kamm, *Biochem. Jour.*, 21, 78; 1927), exhibit a faint but distinct band at 260 $\mu\mu$. They have also discovered that cholesterol purified by a thrice repeated conversion into the dibromide and recovery from same by treatment in boiling alcohol with zinc dust (so-called cholesterol E) can, contrary to the contentions of Windaus and Hess (*Nach. Ges. Wiss. Göttingen, math.-physik. Klasse*, 175; 1927) and Rosenheim and Webster (*Biochem. Jour.*, 21, 389; 1927), still be activated by ultra-violet rays. According to the American workers, this activatability is associated with faint absorption bands at 315 and 304 $\mu\mu$ as well as the three characteristic ergosterol bands.

We are able to confirm the existence of a faint band at 260 $\mu\mu$ in ergosterol, but this is only detected with certainty when a continuous light source is used. As regards the newly observed bands, however, we desire to direct attention to the bands found by us in cholesterilene, which is characterised by selective absorption with maxima at 294, 304, and 321 $\mu\mu$ (*Jour. Chem. Soc.*, p. 47; 1928). The first of these coincides with the 293·5 $\mu\mu$ band of ergosterol, whilst the others are in close agreement with the two found by Bills, Honeywell and MacNair in their specially purified cholesterol. Bearing in mind the known instability of cholesterol dibromide (Lifschütz, *Zeit. physiol. Chem.*, 106, 271; 1919), and also the complex nature of its decomposition, we suggest that the two bands observed in cholesterol E may well be due to traces of cholesterilene formed during the purification process. The amount of this hydrocarbon which would be necessary to show the selective absorption under the conditions employed by Bills, Honeywell and MacNair is of the order of 0·01 per cent.

---

[1] Publication approved by the Director of the Bureau of Standards of the U.S. Department of Commerce.

[2] Bills, C. E., Honeywell, E. M., and MacNair, W. A., *Jour. Biol. Chem.*, 76, 251; 1928.

[3] Rosenheim, O., and Webster, T. A., *Biochem. Jour.*, 20, 537; 1926.

[4] Windaus, A., and Hess, A., *Nachr. Ges. Wiss. Göttingen, math.-physik. Klasse*, 175; 1927.

[5] Bills, C. E., and McDonald, F. G., *Jour. Biol. Chem.*, 72, 13; 1927.

The above suggestion in no way invalidates these authors' results regarding the slight activatability of their purified cholesterol, but simply dissociates the phenomenon from the absorption bands at 315 and 304 $\mu\mu$, for cholesterilene is not rendered active by irradiation.

The Nebulium Spectrum in New Stars.

In Nature of Jan. 28, p. 136, Mr. S. R. Pike makes an objection to the density which I have found, by the 'expanding shell' theory for novæ, to be necessary for the production of the nebulium spectrum. Mr. Pike applies the formulæ of the theory of thermal ionisation and finds that it is inconsistent to have the spectra of hydrogen and nebulium present at the determined density and both existing under the same temperature. For coexistence of these substances, defined as 0·1 per cent. H atoms and 0·1 per cent. O^{++} atoms, he finds that a density of about 10^{-7} gm./c.c. is necessary, as against the density of about 10^{-17} gm./c.c. given by me.

I believe that the entire discrepancy is due to the inapplicability of the theory of thermal ionisation. This theory as developed assumes a condition of thermal equilibrium, and it does not seem possible that equilibrium would have been reached in a few days after the outburst of a nova. Also, one might expect that photoelectric ionisation would be an important factor, especially in considering gases of very low density near a hot star. Furthermore, Mr. Pike's arguments might be extended to the nebulæ as well as the nova shell, in which case one would expect densities of the same order of magnitude, about 10^{-7} gm./c.c. Such a density would be comparable with the mean density of the giant stars, and would indicate that the masses of the nebulæ are enormously greater than has been generally accepted.

It seems to me that a method for studying the coexistence of spectra in novæ would be similar to that followed by Milne (*Mon. Not. Roy. Ast. Soc.*, **84**, 354; 1924) in his study of the life of a Ca^{+} atom, and combining with it some additional suggestions given by Eddington (*Mon. Not. Roy. Ast. Soc.*, **88**, 134; Dec. 1927), where he shows that the dilution of the exciting radiation may account for the 'forbidden lines' of an atom being as strong as its ordinary lines. The problem is very difficult, as one knows nothing of the extreme ultra-violet radiation of novæ.

I should like to take this opportunity to correct a statement in my communication in Nature of Jan. 7, p. 12. Referring to the coefficients of $\rho_0 r_0^2$ in the densities of the nova shells, it was stated that the constancy indicates that the novæ originate from stars of similar physical conditions. That statement can apply only to the radius of the star and the density of its atmosphere.

Science Teaching in Schools.

In Nature of Feb. 25 appears a stimulating article by H. E. A. on "The Range of the Scientific Faculty," with most of which all interested in the pursuit of science will agree. In directing attention to the absence of scientific appreciation on the part of the literary man, a view so ably propounded by Sir Richard Gregory in his presidential address to the Science Masters' Association in January last, the author is performing a public service. Unfortunately, it is doubtful if Nature, despite its literary charm, will find its way into the temples of those deficient in 'factor X.'

What, however, are we to say of H. E. A.'s indictment of the schools in the latter part of his article? He writes . . . "The teaching of science is a failure, because it is parrot work . . .; because it is so far beyond the common intelligence and the teacher's." Again, . . . "No attempt is made in the schools to teach the simplest elements of scientific method. . . ."

Surely H. E. A. cannot mean these statements to be taken seriously. If he does, we are entitled to ask where he has been hiding during the last twenty years. Has he fallen asleep like Rip van Winkle and just wakened up thinking things are still as when he commenced his slumbers?—and meanwhile the precious leaven of Armstrong's heuristic method has been at work with far-reaching effects on science teaching in the schools. Still more important, has he ever tried to teach in a modern school, and has he visited several of these much maligned institutions and seen the science masters at their work?

The brilliant young researchers at the National Physical Laboratory and kindred places, and those making good in the field of industry and in the fight against disease, drawn as they are from all types of secondary schools, are in themselves a tribute to the work of the science masters, who have been responsible for introducing them to the method of science.

The chief canon of scientific method is to make generalisations only when supported by overwhelming evidence.

Is it not as necessary for H. E. A. to be scientific in the full sense of the word when passing judgment on a section of the community as in expressing opinions regarding the effect of 'hydrone' in chemical combination?

E. Nightingale.

St. Albans, Mar. 3.

Several recent leading articles in Nature have criticised the scope and character of science teaching in schools, and with much justification. In a leader in the issue of Feb. 25, two statements are made by H. E. A., namely: that

(1) "the schools say they are in the hands of the universities, whilst these retaliate that they are subject to the schools."

(2) "The Science Masters' Association has neglected great opportunities in the past half-dozen years of discussing the problems, when at Oxford and Cambridge, with the authorities."

Both these statements are true, and something should be done at the next meeting of the S.M.A. at Cambridge. A haphazard discussion is, however, useless. Definite proposals must be made, and if possible a select committee appointed to discuss them. Nature, being almost the only authoritative journal read by dons and schoolmasters alike, could urge this most effectively.

Science masters may suggest, but they cannot act alone. The pace in the schools is set partly by the School and Higher Certificate Examinations, but principally by the entrance-scholarship papers. No school can afford to ignore these without penalising its potential scholars. The same *impasse* has been reached as in disarmament conferences; all desire to reduce the standard, but each is afraid to begin.

How furious the pace is in the schools is not realisey by everyone, least of all perhaps by the university examiners. The School Certificate is a very elementary examination; and it is right that it should be. A specialist course at most schools starts after the School Certificate has been obtained, or an equivalent standard reached, and lasts on an average for two years before the scholarship examination is taken. In this short space of time it is apparently thought desirable that an amount of knowledge should be imparted, which, if really digested, would certainly assure the candidate a first-class degree in natural science without any further preparation whatsoever. Looking through a few chemistry papers set recently at one group of Cambridge colleges, I find questions on the alloys of mercury and potassium, ionic transport numbers, the manufacture of lithopone, and the synthesis of dimethylacetic acid. Remember that at least two other subjects have to be taught as well, that practical work is involved, and that the school time-table will certainly include some study of literature and modern languages.

I submit that to set questions of this kind, and to talk in the same breath of the necessity of acquiring a sound grasp of scientific method (which would of course involve a considerable amount of historical work), imply either insincerity or a painful lack of imagination. Many science masters, it is true, do their best to impart method and principle, but they have to do so always with one eye on the clock. Certain examiners, again, are endeavouring to set questions which seek to probe the 'chemical sense' of examinees; but little advance can be made in this direction until some sort of agreement and uniformity are obtained. At present a really promising boy may be taught—on paper—the reactions of ethyl acetoacetate; he may remember (with luck) how to calculate a transport number; he may even, if he has worked very hard, be able to analyse successfully a mixture of sodium stannate, nickel chromate, and cobalt phosphate. But he will almost certainly be unable to bore a cork or to investigate a simple inorganic reaction unless he knows the answer beforehand; and he could not possibly explain the essential points of difference between the atomic theories of Dalton and Demokritos. Conversely, if he can do these things, he will be woefully ignorant of lithopone and the mercury-potassium alloys.

It is to be hoped that NATURE will not cease from castigating schools and universities until some return to sanity is effected; and that that return will come speedily, before our more progressive pedagogues start teaching quantum mechanics and stellar chemistry in anticipation of the scholarship papers of 1935.

A. K. GOARD.

Marlborough College,
Mar. 5.

No one could be better qualified than H. E. A. to write upon the value of a mind which combines scientific and literary gifts, for we all read his essays and discourses with interest and pleasure. I regret, therefore, that he should have dragged into his essay "The Range of the Scientific Faculty," which appeared in NATURE of Feb. 25, his well-known views upon the science teaching in universities and schools. He says, "The teaching of science in our schools is a failure, because it is parrot work, not scientific; because it is confined to special subjects—chiefly chemistry and physics—geology, botany, and biology being all but neglected."

I have formed the impression that H. E. A. objects strongly to deductions which are not derived from scientific observation and reached by scientific method. He says, "No attempt is made in the schools to teach the simplest elements of scientific method." Could H. E. A. give us the observations and facts on which his statements about the methods used and the subjects taught in schools are based? Would it be fair to ask him how many schools he has personally visited and inspected during the last five years? And is his opinion that the schools "are controlled by people who only know the old knowledge and are without understanding of scientific method" based on personal acquaintance with the heads of schools, or at least on first-hand knowledge of their methods? I am interested to know whether in making these statements he has conformed to his own canons of scientific method.

I cannot claim to have first-hand acquaintance with the work of more than a few schools, and I agree that our work in science could be improved by co-operation with the universities. But, lest a wrong impression of the work of schools should be left by H. E. A.'s remarks, I do think it fair to say that, to the work of some schools, H. E. A.'s statements do not apply, at least so far as the subjects taught and the aims sought are concerned. My own impression—which I cannot claim to be more than impression—is that H. E. A.'s generalisation upon the science work of schools and their heads at the present day fails to do them justice.

F. S. YOUNG.

The College, Bishop's Stortford,
Herts, Feb. 25.

MY cordial thanks are due to the writers of the above letters for their welcome support. The evidence I have of the general accuracy of my indictment is so overwhelming that I must ask that it be taken seriously. If anyone will tell me of schoolwork in progress anywhere to teach the elements of true scientific method, *as applied to ordinary life and to ourselves*, I shall endeavour to see it and be more than glad if I can report that there are exceptions that 'prove my rule,' showing that such teaching can be and is given. Probably I differ from most in my definition of 'scientific method' and shall not easily be satisfied. Reference is made to the heuristic method. Surely this was ruled out years ago, at least by Mr. Wells, as 'food unfit for the Gods,' because of the time needed to digest it. He has never found this, I judge.

I do not blame teachers in schools but the callous system which produces them and the immoral system under which they are forced to work. Nearly everywhere they are the tools of the class deficient in factor X. I particularly blame those who have taken the life and morality out of education and both professionalised and commercialised it from top to bottom. As factor X now governs the world, the class which has it not must be relegated to offices which it can hold with efficiency; we cannot with safety remain much longer under the governance of ignorance. The late President Woodrow Wilson seems to have been an outstanding example of the class. From his "Biography" it is clear that he all but went out of his way to avoid reading anything which would have informed him of the modern advance of knowledge. We need not wonder that we were led into such quandary at Versailles.

My desire was not to direct attention to the absence of scientific appreciation from the literary man. Considering his inborn limitations, he is a good enough, companionable fellow in his way, far more so generally than he who is bitten with the scientific afflatus. My essential contention is, that he is an ear out of which the purse embracing 'science' contemplated by Sir Richard Gregory cannot be made. In the epilogue to Vol. 2 of Sir Sydney Lee's Biography of our late King Edward, we are told—"Literature and science he could not appreciate. . . . *Son métier était Roi.*" So it is with most of us—each of us has his inborn *métier* and must cultivate his own special garden with its peculiar soil. Sowing words, the literary can only reap words.

The chief point I desire to make is, that the body scientific has its fate in its own hands and must be trained to do its own literary work. Frenchmen show us that this is possible. Our Royal Society *Proceedings*, at the present moment, are standing proof that the oncoming generation, especially that raised at the ancient universities, has not yet 'learned the trick' of sane and satisfactory expression. It indulges in fatuous futilities of language which cannot be rationally construed. The practice would be of small consequence were it not that the use of an ill-conceived jargon by scientific workers is producing an ever-widening breach, not only between us and our literary brethren and the public but also within our own ranks. Unfortunately, those who thoughtlessly so misdemean are thereby aiming at inclusion within the Society—once within its ranks they will but spread the disease. On the other hand, a secretary of the Society can entrance an audience with a polished rhapsody upon 'Candle-ends,' whilst his rival at Cambridge outvies him in declaiming the merits of their Snarkian variant, 'Toasted cheese'; he is even acclaimed of *The Times Literary Supplement*, because of the perfection of the language in which he depicts the vagaries of the fully stripped proton (sex undetermined) in presence of a crowded following of loose electrons. Sir J. J. Thomson, in like manner, can thrill the young things at Girton with an account of the new shingled electron and its waved front.

Such is the power of words—owing to this high-brow advocacy, Candle-ends, Toasted-cheese and Electrons, shared and unshared, shingled and unshingled, are now made the standard diet of the schools. Meanwhile, the boy leaves unable to bore a cork and with no proper regard for energy, for water, for air, for coal, for food, let alone his own body. *Moral*: in attempting in schools to teach what we are pleased to call science, we must also give training in the art of simple direct expression; only in this way can proof be given that what is learnt *is* learnt. Does any teacher anywhere do this? They all say 'there isn't time.' At least, we might seek to rank with the notable profession of bath-chair propellers, who are notorious, we have been told recently, for their literary tastes.

It is imperative that the schools and the universities now discuss the problem of examinations together. A beginning should be made at the next meeting of the Science Masters' Association at Cambridge. As a past-president, if the Association will so charge me, I am willing to undertake to present a considered report upon the situation, to include constructive proposals, if possible. Such a report might serve as the basis of a general discussion. A beginning must be made somewhere and by someone, if we are ever to secure an efficient scientific service in the schools. The decision should be made forthwith, as the task of preparation will be a long and difficult one.

H. E. A.

The Nature and Function of Golgi Bodies.

In the *Proceedings of the Royal Society*, B, vol. 97, 1924, is a paper by Prof. Subba Rau, Dr. Rogers Brambell, and myself, entitled "Observations on the Golgi Bodies in the Living Cell." In this paper (unnoticed by Prof. Walker) we have given photomicrographs of the Golgi apparatus in living and stained cells. More than this we cannot do, except to ask those zoologists and physiologists who may be interested in this problem to read this paper and to examine the material we have used ourselves.

With regard to Dr. Ludford's letter in Nature of Feb. 4, p. 169, I might point out that Golgi bodies are visible not only in molluscs, but also in annelids. In the ovary of the common earthworm both mitochondria and Golgi bodies can be followed throughout oogenesis, in freshly dissected ovaries, untreated by stain or fixative (Gatenby and Vishwa Nath, *Quart. Jour. Micr. Sci.*, vol. 70, Part III. Sept. 1926).

Prof. Walker in his latest letter (Nature, Feb. 25, p. 279), as well as in his former ones to Nature, takes the view that because certain emulsions treated by modern cytological techniques reveal objects resembling Golgi bodies, therefore the latter are artefacts. This is a curious position to take up, especially in view of the fact that in his last letter Prof. Walker shows that he has not examined Helix ovotestis cells. As a matter of common knowledge to all cytologists who have taken the trouble to examine such cells, the *nebenkern* batonettes (Golgi bodies) and mitochondria alone show well in fresh cells, the archoplasm being too transparent to be seen easily. This fact is proven by the paper of Rau, Brambell, and myself, by means of photomicrographs of dead and living cells, and can be confirmed by any student of microscopy who cares to examine snail spermatocytes, fresh, stained in Janus Green or Dahlia, or treated by any of the modern techniques for the cytoplasmic inclusions.

Now Prof. Walker's original position was that *both categories of cytoplasmic inclusions are artefacts*. In his printed paper he merely claims that the Golgi bodies alone are artefacts. But how does he explain the fact that with the technique upon which every modern text-book account of spermatogenesis is based, *both mitochondria and Golgi bodies appear constantly side by side*? The technique I refer to is chrome-osmium iron hæmatoxylin, with which almost all the work of Bowen in America, Schütz in Russia and Switzerland, and Hirschler in Poland, was done, and which the British cytologists have used constantly. This technique is merely the old Flemming and iron hæmatoxylin with the acetic acid left out or much reduced (Meves' fluid). How does Prof. Walker explain this fact? How could the Golgi bodies be artefacts if the mitochondria are not also?

How does Prof. Walker explain away the following fact? If one takes a fresh preparation of snail cells, and runs chrome-osmium fluid under the cover-slip, one can see the Golgi bodies and mitochondria being fixed *in situ* and in the light of day. The subsequent staining in iron hæmatoxylin merely blackens the same bodies one saw *intra vitam*. Will Prof. Walker explain where the catch comes in? Has he tried this experiment himself?

How does Prof. Walker explain the following fact? Take any tissue, from invertebrate or vertebrate, fix and stain by a Golgi apparatus method, and if the method has been used properly, a Golgi apparatus always appears in the same place in the same kind of cells. It is *not* a matter of a precipitate here or a precipitate there, haphazard. How then does Prof. Walker explain the constancy of position of these Golgi bodies in given cells?

Will Prof. Walker explain the following fact? Golgi bodies have been described by workers in every civilised country, *from all orders of animals*. The work of Bowen on plants brings the latter into line with animals. Will Prof. Walker say that all this work is incorrect? Prof. Walker has criticised modern cytological technique. Will Prof. Walker explain at what step the artefacts are produced, and *indicate a technique which he considers better?* Is it corrosive acetic or Bouin's fluid, or is it Carnoy?

Was the Moore and Walker paper on mammalian spermatogenesis ("Liverpool Cancer Report," 1906) done with a better technique than we have to-day? I think not! The cells described and drawn by these workers are merely wrecked skeletons of their former selves! The proteid structures are twisted and distorted, and there is scarcely any lipoid left in the cells.

Now it would be regrettable if anyone, zoologist or non-zoologist, were to entertain the idea that Prof. Walker has any support from cytologists. His views, so far as modern cytology goes, are unique. They will remain unique as time goes on, for modern cytological technique is logical and takes into account our biochemical knowledge of the solubilities of lipoids and other subtle cell bodies. We can explain every step in what we do. We get results which agree with the intra-vital appearance of the cell, and it is unlikely that further gross improvements in cytological technique will be made. J. BRONTË GATENBY.

Trinity College, Dublin, Feb. 28.

CERTAIN of Prof. Walker's assumptions (NATURE, Feb. 25, p 279) are opposed to direct observation. Thus his idea that the archoplasmic vesicles and Golgi bodies are one and the same thing is quite untenable in the light of recent work (see J. Hirschler, *C.R. Soc. Biol.*, 98, No 2, 145-6; 1928).

Prof. Walker has ignored one significant feature, that in many cells, for example, gland cells, the Golgi apparatus occupies a definite position between the nucleus and the lumen. When the gland is stimulated to activity the Golgi apparatus enlarges, while still retaining its relative position with regard to the nucleus. That is to say, we have within the cytoplasm a specific area capable of precise experimental modification. On the basis of Prof. Walker's own views, one would have to assume that the lipins of the cell are collected in this specialised area. It is this part of the cytoplasm that is called the Golgi apparatus. R. J. LUDFORD.

James Gregory, John Collins, and some early Scientific Instruments.

DR. R. T. GUNTHER has described (*Archæologia*, vol. 76, p. 273) scientific instruments belonging to the University of St. Andrews which were exhibited in the Lewis Evans Collection at the Oxford meeting of the British Association. The St. Andrews instruments include the two-foot astrolabe by Humphrey Cole, dated 1575, "the finest extant Elizabethan scientific instrument"; an armillary sphere, also by Cole, 1582; an old Dutch or Flemish circumferentor; and a sea-astrolabe, or mariner's astrolabe, with one quadrant divided diagonally, inscribed "Elias Allen Fecit 1616."

Ever since Dr. Gunther directed attention to the value of these instruments, I have been puzzled to account for the way in which they came into the possession of the University. Facts have recently emerged which go far to establish the theory that they were purchased by James Gregory, the inventor of the Gregorian telescope, in 1673. A Commission from the University authorities "to Mr. James Gregorie, Professor of Mathematics," dated June 10, 1673, empowers him to select and buy "such instruments and utensils as he with advice of other skilful persons shall judge most necessary and usefull for the above-mentioned design." [providing ane observatory]. An interesting sidelight on this episode is afforded by an extract from the Burgh Records of Aberdeen for Oct. 15, 1673, from which it appears that "seeing the said professor was ane town's man heir . . . the councell . . . appoynts ane collectione to be at the Kirk dores . . . the nixt or subsequent Lord's day for the forsaid effect [for the Observatorie at Saint Andrews]."

In a letter to Collins, dated Feb. 15, 1669, Gregory had asked for a divided quadrant and a brazen sector, and in letters written in 1672 and 1673 he speaks of visiting Collins in connexion with the purchase of mathematical instruments. In a letter from Newton to Collins, Sept. 17, 1673, the former writes: "I understand that Mr. Gregory is at London, and intends to make Cambridge in his way into Scotland" (Rigaud, "Corr. of Scientific Men," vol. 2). On April 30, 1674, Gregory writes to Rev. Colin Campbell: "It wer tedious to write down particularlie all the instruments I have brought home, yea a larger letter would not contein all ther names and sizes, for I have of all sort: our largest quadrant is of oak, covered with brasse, 4 foot in radius and actually divided in minutes, of which we can judge $\frac{1}{2}$ or $\frac{1}{4}$: we have two semi-sextans, all of brasse, 6 foot in radius, diagonally divided, in which we can judge $\frac{1}{8}$ or $\frac{1}{4}$ of a minut: our largest telescope is 24 foot long; which magnifys one dimension of the object 100 times" ("Archæologia Scotica," vol. 3, p. 275, 1831). Gregory says: "the instruments ar keeped in the bibliotheck," but of those mentioned there is now no trace, although Gregory's clock is still in the University Library and through the building passes a meridian line which he constructed.

The observatory at St. Andrews never materialised, and in 1674 Gregory received a call to the College of Edinburgh, which he accepted. He died suddenly before he had been a year in his new home.

The suggestion that the Cole astrolabe was purchased by Gregory during his visit to Collins is supported by the fact that the instrument of 1575 is accompanied by a tablet inscribed "John Marke fecit lat: 56° 25′" Dr. Gunther remarks that John Marke flourished about 1668 at the sign of the Golden Ball, near Somerset House, where he sold Collins's quadrants of paper gummed on plates of copper and varnished (*Phil. Trans.*, 1668). The latitude of St. Andrews is actually 56° 20′, but it is doubtful whether Gregory had instruments for an accurate determination before his visit to London. Even after his return he writes, "the latitude here is 56° 22′."

I take this opportunity of correcting a mistake in my article in NATURE of Feb. 18, p. 238, to which my attention has been directed by a correspondent. Relying upon A. G. Stewart's "Academic Gregories" (p. 28), Collins was referred to as a secretary to the Royal Society. He was elected a fellow of the Society on Oct. 24, 1667, but was never secretary

H. S. ALLEN.

The University, St. Andrews.

PROF. STANLEY ALLEN has put forward a very satisfactory working hypothesis to account for the presence of these early English instruments at St. Andrews. The additional plate supplied by John Marke proves that the Cole astrolabe was in the hands of this eminent maker in London about the time when Prof. Gregory was collecting scientific instruments there. May I add that the finest picture of Cole's great astrolabe was published in colour in the *Illustrated London News* for Aug. 14, 1926.

R. T. GUNTHER.

The Old Ashmolean,

Light and Sight.

IN a recent number of NATURE (Jan. 21, p. 95), Sir John Parsons, referring to the duplicity theory of vision, says without qualification that the "rods are responsible for scotopic, the cones chiefly for photopic vision," though he later refers to 'difficulties' in this formulation.

Current theories of colour vision may be divided into two groups: Young-Helmholtz (three-colour processes, all positive) and Hering (two-colour processes, with positive and negative conditions, and white). The first logically leads to a postulate of three photopic light-sensitive pigments, and a fourth for scotopic vision.[1] Following this scheme, it is logical to assign the four pigments each to a separate series of organs, and to assign scotopic vision to the rods, which alone have been recognised as possessing the scotopic pigment. The photopic pigments should be present in such minute amounts as to be undetectable with our present crude methods.

The Hering theory, with its negative as well as positive colour-processes and its double maximum for the red process, leads as naturally to some physical (refraction, interference or diffraction) separation of the colours, and a single, indifferent photopic pigment is sufficient (the same which any theory seems to demand for the peripheral retina). In this case there is no obvious reason why the two pigments, photopic and scotopic, should coincide in distribution with the presence or absence of the special structures leading to colour separation, and Sir John Parsons's statement is no longer obvious.

In fact, the existence of an acute colour sense in the middle range of adaptation[2] (that of ordinary lamp-light), where the rapidity of adaptation shows that the scotopic pigment is functioning, seems incapable of explanation unless this independence is assumed. Under the Helmholtz theory, the colour-processes, being dependent quantitatively on the minute surviving amount of photopic pigment, should be completely overshadowed by the ten or a hundred times greater activity of the 'rods.'

I have recently worked out in some detail a hypothetical separation of the colour-sorting and photosensitive processes on this basis of independence, with a physical basis (interference) for one and a chemical (photosensitive pigment) for the other (*American Journal of Psychology*, **40**, 1-25; 1928).

As to the foveal 'cones,' it should be noted that they are really organs of intermediate character, at least in the monkey and man, and could just as well be interpreted as modified *rods*.

WM. T. M. FORBES.

Cornell University, Ithaca, N.Y., U.S.A.

---

[1] It is necessary to assume for the peripheral retina either a fifth pigment or an equal mixture of the three colour pigments in the individual rods.

[2] I propose to call this middle range of adaptation 'mesopic.' Most experimental work is done within it, but may be reported either as 'photopic' or 'scotopic,' causing much confusion of interpretation.

The 'Dative' Chemical Bond.

WAVE mechanics notwithstanding, the electronic conception of valence in chemistry is serving a useful purpose. It is true that we know little in regard to what we symbolise by a shared pair of electrons, but even less was ever known of the inner meaning of the single bond of organic chemistry, although nobody would deny that the conception of such a bond has been a useful one.

In recent years, a clear distinction has been drawn between two types of co-valence involving a pair of electrons shared by the atoms *A* and *B*. In the first type, 'normal' co-valence, each of the two atoms contributes one of the two electrons. In the second type, one of the two atoms, say *A*, contributes both electrons. Since *B* gains a share in the pair, it gains in negative charge; while *A* loses in negative or gains in positive charge. Because of this separation of charges, the molecule is rendered polar.

Various names have been suggested for the second type of co-valence here described. So long as the conception remains a useful one, by all means let us have a good name for it. One of the earliest names, suggested in 1921 by Perkins in the *Philippine Journal of Science*, was a 'borrowing direct union.' Lowry proposed the names 'mixed' or 'ionised' double bonds, because the union partook of the nature of electro-valence as well as of co-valence. These names have been adversely criticised by Porter, Rankine, and others. Sugden in 1925 proposed the term 'semipolar double bond,' which is perhaps unduly polysyllabic. Realising that none of these names is entirely satisfactory, Sidgwick called this type of bond the 'co-ordinate' link or bond. But this is apt to lead to confusion, in such a typical case, for example, as the following. In considering the compound $[Co\,Cl(NH_3)_5]Cl_2$, chemists now universally follow Werner's usage and speak of the chlorine and the five ammonia molecules within the square bracket as being co-ordinated with the central cobalt atom. But of these six co-ordinated entities, only five are attached by 'co-ordinate' links.

Adopting a useful terminology, Sidgwick has called the atom *A* above a 'donor' and the atom *B* an 'acceptor' atom. To this it cannot be objected that the names savour overmuch of electro-valence, where one electron is given and taken, for the second type of co-valence has indeed a close analogy to electro-valence, and this may rightly be indicated in the nomenclature. In consonance with this idea, I wish to suggest that the second type of co-valence bond described above be called a 'dative' bond or link. 'Dative' is a short word, and unspoiled by previous usage in chemistry.

ALAN W. C. MENZIES.

Princeton University, Feb. 4.

Luminescence of Mercurous Chloride of Standard Purity.

ON studying the photochemical changes of a pure and dry mercurous chloride, prepared in a dark room, a greenish-white luminescence was observed when this was stirred by a dry glass rod. This phenomenon was noticed in glass, porcelain, and metallic crucibles for about five seconds, and it was not possible to produce it with the same rod again unless the rod was cleaned of its deposit of mercurous chloride powder. The luminescence was produced also for about the same length of time if the rod itself with its thin mercurous chloride cover was slightly rubbed with a dry cloth. The foregoing illumination of the sample has no effect on the duration and quality of the excited light.

The experiments so far made show that the dryness of the sample treated plays an important rôle in the intensity and the duration of the phenomenon described. On the other hand, one could not increase the duration of scintillation, although all traces of water and other impurities were most carefully excluded both in preparation of the chloride used and during the operation with it.

So far as could be proved, the phenomenon observed is not caused by electric charge produced by rubbing, nor is it a case of phosphorescence or crystalo-luminescence, since it is affected neither by a previous illumination nor by a perfect pulverising.

The details will be published elsewhere after the experiments have been completed.

The New Science Museum.

THE Science Museum, which is the national museum of science and industry in Great Britain, dates from 1856, when the various collections which had been acquired by the Royal Commission of the Exhibition of 1851 for the purpose of illustrating the application of science and art to industry were brought together and arranged for exhibition at South Kensington The exhibition so formed was housed in temporary buildings and was known as the South Kensington Museum, which title it retained for more than half a century. In 1909, that part of the collections pertaining to art was transferred to the newly constructed Victoria and Albert Museum, and the science collections which remained were brought under a separate administration. The Science Museum from that time ceased to be a purely departmental institution and became a national one; its new aspect was emphasised by a Departmental Committee, which reported in 1911 and 1912 on its scope and aims, recommending the erection of new buildings to provide a very considerable addition to the area of the exhibition galleries. The erection of the first block of the new buildings was begun in 1912, but, owing to the War, its completion was indefinitely postponed and the development of the collections was retarded. This portion, the Eastern Block, has, however, now been completed and was opened by His Majesty the King on Mar. 20.

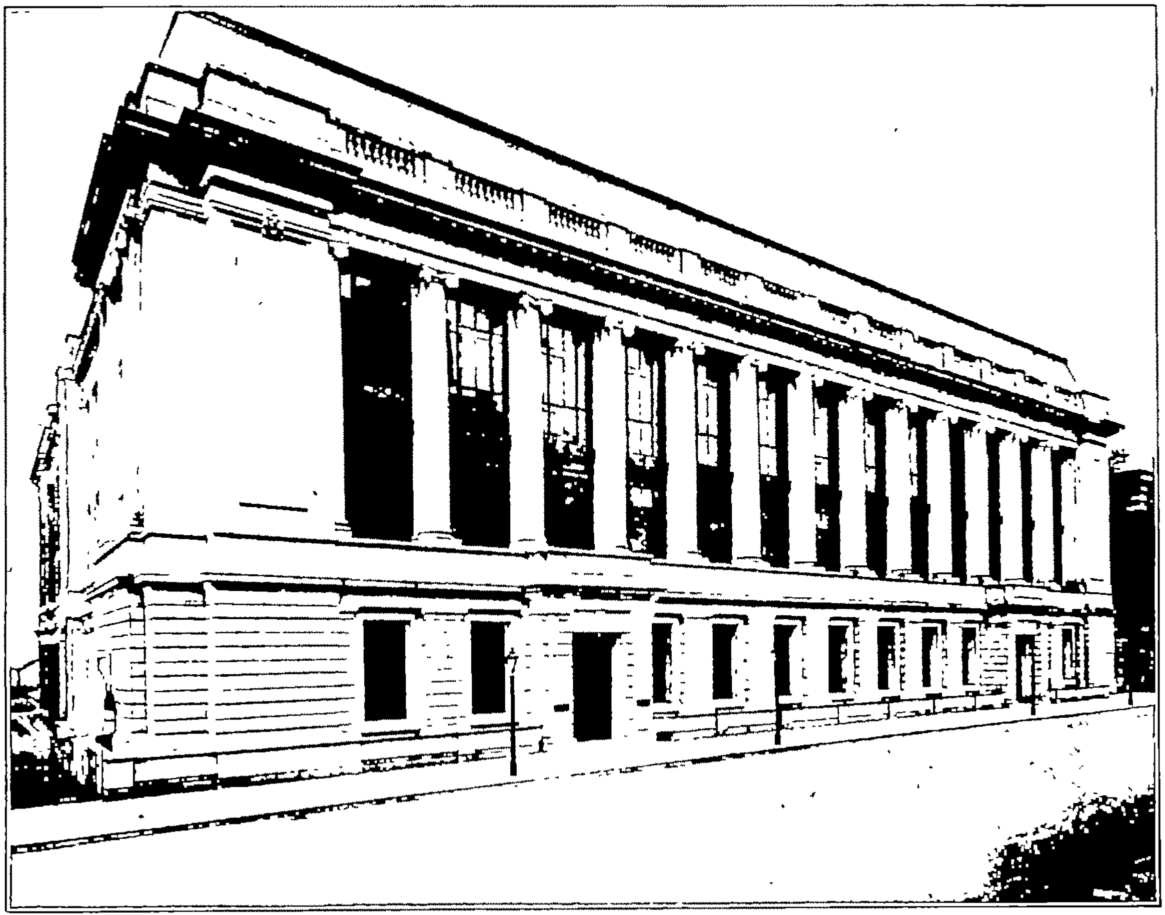

Fig 1.—New buildings of the Science Museum, South Kensington. East block, from Exhibition Road.

The main object of the Museum is to illustrate science and the application of science to industry, and for this purpose the collections are grouped broadly under four divisions: (1) Industrial engineering; (2) stationary engines and land transport; (3) water transport and air transport; (4) science and scientific apparatus. This classification (and that of the many groups within these divisions) is not strictly logical, but is determined largely by the conditions of space and by the history of past development, and will be subject to revision when that is possible. In the various groups or sections development takes place in accordance with a system introduced by the present Director, Sir Henry Lyons, which provides approved schemes of development to include a historical series of critically selected objects which will illustrate the most important stages in the past development, and also a series illustrating current practice. Without some such clear plan, museum collections tend to become ill-balanced, some parts being over-represented and others comparatively neglected. The historical series changes but slowly, and should contain all objects of enduring importance; in the representation of current practice the objects are of necessity changed frequently, being replaced by newer or more efficient examples as these are produced. In this way it is possible to maintain the collections representative in character without their becoming unmanageable in size.

The objects forming the collections are obtained by gifts, loans, purchases, or by construction in the Museum workshops. During recent years the number of acquisitions annually has been from about 1200 to 1500, and of these 90 per cent. are gifts and loans. The funds allotted for the purchase of objects are only £800 per annum, so that the number of exhibits thus acquired is small. A descriptive label, which gives both a general and a technical description of the exhibit, is placed with every object, and illustrated catalogues of the various sections are published. Models, apparatus, and machinery are shown in motion whenever this is practicable; in many cases exhibits are sectioned in order that the internal construction may be seen. The collections of the Science Museum are very rich in examples of original historical apparatus; they contain full-sized machinery and apparatus whenever possible, and accurately executed scale models when space must be restricted.

The new building has galleries providing an exhibition area of approximately 143,000 square feet —a little more than one-third of the area recommended as ultimately necessary—a main entrance hall, demonstration rooms, offices, workshops, and stores. The exterior is in Renaissance style, while the interior is simple and devoid of ornamentation, giving a suitable setting for the exhibition of machinery and scientific apparatus. Particular attention has been paid in the design to the special needs of the Science Museum; the average ratio of glass to floor area is about 1 : 4, excluding glass roofs, and the floors are provided with an elaborate system of ducts which accommodates the lighting, gas, and compressed air mains, and enables the power necessary for operating models, etc., to be available readily.

The main entrance in Exhibition Road opens direct into a reception hall from which access is given immediately into a top-lit lighting hall 120 feet long and 40 feet wide, roofed at third-floor level and bounded on all sides by other exhibition galleries. This hall is devoted normally to stationary engines, and contains, among many historical exhibits, three of the original engines designed by James Watt. The important inventions of Richard Trevithick in the development of the high-pressure engine are well represented, but the collection covers the whole period from the primitive application of animal power, wind and water wheels, to the modern steam turbine and internal combustion engine.

A roof-lit gallery adjacent is devoted to railway engineering generally, and contains a very representative series of models illustrating many types of locomotive engines as well as the original *Puffing Billy*, *The Rocket*, and other historical engines. At the west end of this gallery is a reproduction of James Watt's attic workshop, in which at Heathfield, Birmingham, he did experimental work on sculpture-copying machinery during the latter years of his life. The contents are placed exactly as they were left by him at the time of his death in 1819.

Another gallery on the ground floor accommodates the aeronautical collection, which includes, among several historical machines, the original Wright aeroplane of 1903—the first man-carrying aeroplane to make a free flight under power—and the Vickers-Vimy trans-Atlantic aeroplane of 1919. A series of more than one hundred models illustrates the development of lighter-than-air and heavier-than-air craft up to the present day, and the progress made in aero-engine design is adequately shown.

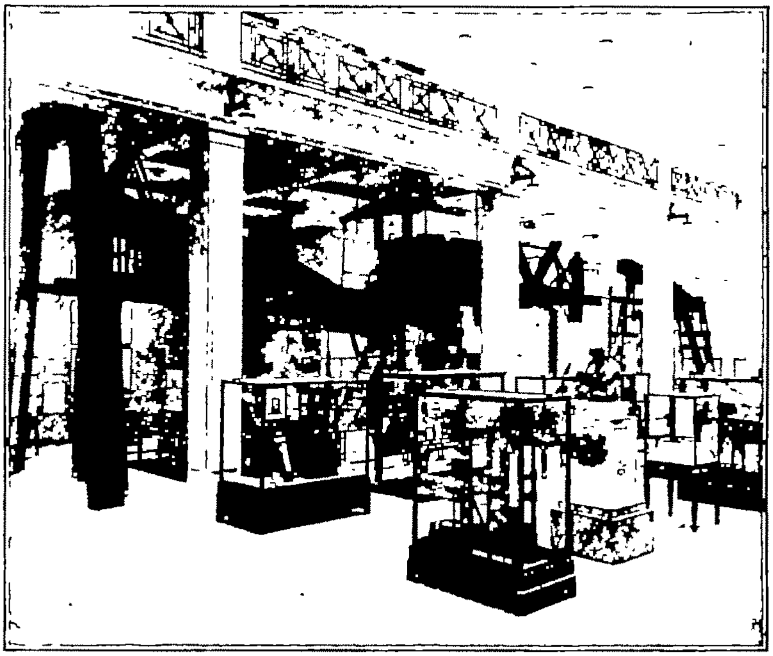

FIG. 2.—Stationary engines and prime movers.

The collections illustrating electrical engineering, electrical communication, hand tools and machine tools, mining and metallurgy, textile machinery, and a part of ship construction are shown in the first-floor galleries. In electrical engineering there is a valuable collection of early dynamos and electrical machinery, with examples of modern practice. A modern automatic telephone exchange system is arranged for demonstration and may be operated by the public. A receiver for radio telephony is arranged also for operation in order to demonstrate modern distortionless reproduction. In the hand and machine tool collection the development of some of the more common tools is shown from the earliest civilisations down to the present day. Textile machinery is represented by some very valuable original machines made by Arkwright, replicas of Hargreaves' spinning jenny and Crompton's mule, with models and actual machines showing the various stages in spinning and weaving.

The Eastern Gallery on the first floor contains a historical series of models tracing the development of the sailing ship from the Viking long-ships to the great three-deck sailing ships of the Crimea War on the naval side, and to the Australian wool-clippers on the mercantile side. Many of the models are contemporary, such as that of H.M.S. *Prince* (1670), and have been made in the actual yards when the ships were built. Another series of models shown here illustrates, in considerable detail, the development of the armoured battleship from H.M.S. *Warrior* of 1861 up to the super-Dreadnought, H.M.S. *Monarch* of 1912, while sectioned models show advances made in internal construction.

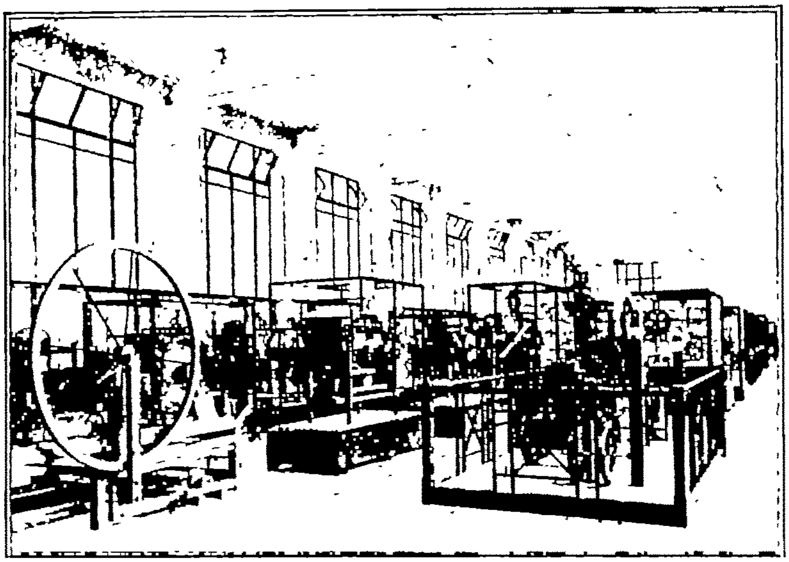

Fig. 3.—Textile machinery.

The corresponding gallery on the second floor contains a series which illustrates the development of the merchant steamship from its infancy to the present day. A particularly fine series of Cunard models shows the growth and improvements of Atlantic liners, while cargo vessels, tank steamers, and their special systems of construction are well represented. The Eastern Gallery on the third floor is devoted to a collection of small craft from all parts of the world, and it gives special facilities for the study of the results produced both by race and environment. The various types of fishing vessels peculiar to the different portions of the British coasts, and now fast disappearing, are illustrated by some models, most of which are at least forty years old. Junks and sampans from China and from Japan, Arabian dhows and dahabias from the Nile, are well represented, while a collection of yacht models traces the development from the Dutch yachts of Stuart times and the pilot cutters of the early nineteenth century to the highly specialised racing yachts of to-day.

Other collections to be found on returning to the second floor are those illustrating meteorology, geophysics, electrical instruments, mathematical instruments, time measurements, pumping machinery, and building construction. In meteorology the development of the various meteorological instruments is shown in a historical series, and the method of computing and producing the daily weather reports of the Meteorological Office is illustrated. The group illustrating geophysics, including atmospheric electricity, terrestrial magnetism, seismology and gravity, is represented by instruments ranging from Choko's seismoscope of A.D. 132 to the modern Milne-Shaw seismograph and the latest models of the Eötvos torsion balance.

The section relating to time measurement includes examples of water-clocks, sundials, clocks, watches, and chronometers, ranging in period from the time-measuring devices of ancient Egypt to modern systems of electric clocks. Of special interest are the representations of a water clock from Karnak of about 1400 B.C. and an Egyptian shadow clock of the tenth to eighth centuries B.C., also the fourteenth century turret clock from Dover Castle. The second of John Harrison's four chronometers, the performance of the last of which obtained the award offered by the British Government for a method of determining longitude, is also shown here.

The third-floor galleries contain the collections illustrating chemistry and industrial chemistry, geography, geodesy and surveying, optical instruments and astronomy. A large gallery adjoining the reception hall, with an entrance direct to Exhibition Road, has been allotted for special temporary exhibitions such as those illustrating the results of current scientific research which have been contributed in the past by the various research associations and have proved of considerable interest. At present this gallery contains the King George III. collection of scientific instruments which was formed during the latter half of the eighteenth century and located in the King's Private Observatory at Richmond until 1841. This collection forms an interesting and valuable record of the state of instrument design and development at that period, and includes instruments intended for serious scientific research in astronomy, electricity, and mechanics, as well as apparatus devised purely for instructional purposes.

Obituary.

SIR AUBREY STRAHAN, K.B.E., F.R.S.

ON Mar. 4 Sir Aubrey Strahan died at the age of seventy-five at his house, Fairfield, Goring, Berks, which had been his residence since his retirement from the directorship of the Geological Survey of Great Britain and the Museum of Practical Geology in July 1920. He had been in fairly good health up to within a few days of his death, and took an active interest in local public affairs, and was a member of the Court of the University of Reading.

Sir Aubrey Strahan was the son of Mr. William Strahan of Blackmore Hall, Sidmouth, and was born on April 20, 1852. He was educated at Eton, where he went in 1865 to the Rev. Herbert Snow's house. In 1870 he entered St. John's College, Cambridge, and took his honours degree in natural science in 1874. His experience at Cambridge moulded the course of his future life, for he was associated with a group of students under Sedgwick, McKenny Hughes, and Bonney, destined to attain great distinction as geologists. Among his friends of those years may be mentioned Teall, Marr, Sollas, and Clough. In 1875 he joined the Geological Survey of Great Britain as an assistant geologist, and in that service he continued for the rest of his active life, ascending through every grade until he became director in 1914. His early work was done in the coalfields of North Wales and in the Isle of Wight, and his interests were principally in Secondary and Carboniferous rocks: all his work was done with painstaking thoroughness and has well stood the test of time.

Strahan was a geologist of sound judgment, little disposed to speculation or hypothesis. His great merits as an authority on coalfield geology received recognition in 1903, when he was appointed a member of the Royal Commission on Coal Supplies. He was one of the most valuable members of that Commission, which produced a report of the greatest permanent value, such as no other country than Great Britain possesses. Since 1897 Strahan had been in charge of the revision of the maps of the South Wales coalfield, which were old and unsatisfactory. This work occupied his attention for nearly twenty years and resulted in the production of a complete series of memoirs, one-inch and six-inch maps of that coalfield, which are recognised as being of a very high standard. With Dr. William Pollard he also produced a memoir on the coals of South Wales, discussing the causes of anthracitisation, which has attracted much attention.

In January 1914, on the retirement of Sir Jethro Teall, Strahan was appointed director of the Geological Survey. Very soon thereafter the country became involved in the War, and the whole of his energies were absorbed in the task of supplying geological information for civil and military purposes. He prepared and issued maps of the Belgian war zone, and undertook a great variety of tasks, both personally and through his staff, in connexion with active operations on all the fronts. In addition to this, the demands for home sources of minerals for industry became very urgent. The staff was greatly depleted by the departure of geologists on active service, but Strahan organised a bureau of information which gradually increased its activities until it took in every part of the field of British economic geology and extended also to many of the Dominions and allied countries. The result of this work afterwards appeared in a series of special reports on the mineral resources of Great Britain, which now comprises thirty volumes and contains accurate descriptions of practically every useful source of economic minerals in Great Britain.

During and after the War, Strahan served on many departmental committees and was much consulted in reference to problems of reconstruction and the development of research in connexion with industry. He aided in the reorganisation of the Geological Survey which resulted from its transference to the Department of Scientific and Industrial Research in 1919, and placed the institution on a much more satisfactory basis.

The maps and memoirs which Strahan prepared in collaboration with his colleagues are far too numerous to mention individually. Among the more important may be cited the memoirs on Chester, Rhyl, Flint, Isle of Purbeck and Weymouth, and the series on the South Wales Coalfield. He was very specially interested in the problem of buried or concealed coalfields in the south-east of England. Several important papers from his pen have appeared in the *Quarterly Journal of the Geological Society of London.*

Among the honours conferred on Strahan were the fellowship of the Royal Society (1903), president of the geological section of the British Association (1904), vice-president of the International Geological Congress (1913), president of the Geological Society of London (1913–14), and the Wollaston medal (1919). He took the degree of Sc.D. at Cambridge in 1907 and was created K.B.E. in 1919.

The distinguishing characteristics of Strahan's personality were his thoroughness and his trustworthiness. His opinions on all questions of geology were given with caution and were very highly valued. The conclusions he arrived at were always founded on very elaborate investigation. Although he did not shun speculation, he was averse to brilliant and elusive hypotheses. He had great charm of manner, and his friendship was much prized. In addition to this he had a shrewd judgment of men and excellent business capacity; these qualities made him a Civil Servant of outstanding distinction, and coupled with an intense love of geological work and a wide knowledge of British geology, they raised him to the highest position in the Geological Survey.

J. S. F.

News and Views.

Dr. Jeans's recent lecture before the Royal Society of Arts, which forms our Supplement this week, affords one more example of its author's remarkable power of presenting the results of the most recondite astronomical research in intelligible and exceedingly interesting language. No one has contributed more conspicuously to the impressive story which it unfolds than Dr. Jeans himself, and the secret of his success, both in investigation and exposition, can be traced in no small measure to the fact that he never loses sight of the universe while examining the stars. He has learnt, as every astronomer and physicist must ultimately do, to think cosmically. It is an awe-inspiring tale he tells, and one which tends to escape critical appreciation by the reason, by virtue of its overpowering effect on the imagination, unless one is careful to repeat to oneself over and over again the warning that "our three-days-old infant cannot be very confident of any interpretation it puts on a universe which it only discovered a minute or two ago." This necessary corrective to our enthusiasm might well receive greater emphasis without risk of chasing the impassioned expression from the countenance of the most poetical of the sciences. There is a danger that the charm and artistic completeness of Dr. Jeans's exposition should cause readers to invest his remarks with a finality which his own intellectual control would not allow him to claim for them. It must be borne in mind that the 'immortal moment' to which he refers is not necessarily the moment of glimpsing immortal truth. A child has two immortal moments—one when he first beholds the sea, and another when he reads "Treasure Island." It is perhaps an open question which is the more worthy of comparison with the present outlook in cosmogony.

Sir Oliver Lodge, on the occasion of Dr. Jeans's lecture, directed attention to the most striking deficiency of our present views, in asking what becomes of the radiation which the stars are continually pouring into space. In the last few ticks of the clock we have learnt where the radiation may come from, but no one has yet been able to hazard even a plausible guess as to where it goes, or is destined to go, in a possibly finite space. Our ignorance on this point may well make us doubtful whether we have yet begun to understand the universe. Can we really say we have begun to understand geography if we have learnt where a river may rise, but remain unaware of the existence of the sea? Dr. Jeans's figures lead to the conclusion that the mass-equivalent of the radiation already discharged must far exceed the total mass of matter now existing as stars and nebulæ. We therefore know nothing of the greater part of the substance of the physical universe. If we have cause for congratulation, it is that we can now realise more clearly than before how inadequately our present conceptions represent reality. That is a great advance—perhaps an essential part of every advance the human mind is capable of making—and the considerations which Dr. Jeans has brought before us contribute substantially to intellectual progress when judged by this standard.

In January 1927 the Australian Development and Migration Commission submitted to the British Government a scheme for a geophysical survey of certain parts of Australia. This scheme was referred by Mr. Amery to the Empire Marketing Board, which invited the Committee of Civil Research to set up a sub-committee to investigate the proposal. Appointed in April last, the sub-committee presented a report which was approved by the Committee of Civil Research in July; the Empire Marketing Board then arranged with the Australian Government to finance the scheme jointly, by equal contributions up to £16,000 each, spread over two years. Already by November last the leader of the survey party had been chosen, namely, Mr. A. Broughton Edge. The report of the sub-committee has recently been issued, under date November 1927, though for press purposes it was 'released' only in February 1928. The report is a valuable and important document, and in the short space of 15 pages indicates where and to what extent geophysical methods of surveying have been employed for economic purposes, what are the principal methods that have been successfully used, with their range of usefulness, and what recent advances in method have been made.

Geophysical surveying methods depend on properties which can be detected without direct access; the chief of these are gravity, electrical conductivity, intensity of magnetisation, and elasticity. They may be used directly to ascertain the presence of bodies of ore which themselves produce measurable effects at the surface, or indirectly in cases where such effects, though not caused by the bodies sought for, are produced by other underground substances usually associated with those bodies. The indirect method has an important application to the location of oil deposits, which appear to be associated with salt-domes, the location of which can be determined directly by geophysical means. The development of such methods has occurred mainly since the War, stimulated by the increasing possibility of working deep deposits, and by the cost and difficulty of borings and shafts for the direct location of deposits. The report indicates in outline how far it is of value to use different methods in conjunction with one another. The specific recommendation is in favour of an experimental survey of a restricted area, say 20 miles square, in Australia; the choice of the area, among the large number which the committee considers are likely to be suitable prima facie, being left for decision by the leaders of the party in consultation with the leading Federal and State geologists, regard being had to the desirability of developing new regions for expansion of population. Detailed recommendations are made as to the personnel, cost, duration,

(Continued on p. 471.)

Supplement to NATURE

No. 3047 MARCH 24, 1928

The Wider Aspects of Cosmogony.[1]

By J. H. JEANS, Sec. R.S.

INTEREST in scientific cosmogony is a recent, and still a very tender growth. Anthropologists and geologists tell us that man has existed on earth for something like 300,000 years; we must go this far back to meet our ape-like ancestry. Between them and us some 10,000 generations of men have walked the earth, most of whom have probably given some thought, in varying degrees, to the significance of their existence and the plan of the universe.

Of these 10,000 generations of men, the first 9990 unhesitatingly regarded the earth as the centre, and terrestrial life as the central fact, of the universe. As was suited to its majesty and dignity as the abode of man, the earth stood still while the celestial sphere spun round it, covering in the earth much as a telescope-dome covers in the telescope; and this dome was spangled with stars, which had been thoughtfully added so as not to leave the central earth unillumined at night. Ten generations at most have been able to consider the problem of their existence in anything like its proper astronomical perspective.

THE POSITION OF MAN IN THE UNIVERSE.

The total age of the earth far exceeds the 300,000 years or so of man's existence. The evidence of geology, and of radio-activity in rocks in particular, shows that it must be something like 2000 million years, which is several thousand times the age of the human race. Old Mother Earth must regard man as a very recent apparition indeed; he has just appeared to burrow into her, burn her forests, put her waterfalls into pipes, and generally mar the beauty of her features. If he has done so much in the first few moments of his existence, she may well wonder what is in store for her in the long future ages in which he is destined to labour on her surface. For in all probability the life in front of the human race must enormously exceed the short life behind it. A million million years hence, so far as we can foresee, the sun will probably still be much as now, and the earth will be revolving round it much as now. The year will be a little longer, and the climate quite a lot colder, while the rich accumulated stores of coal, oil, and forest will have long been burnt up; but there is no reason why our descendants should not still people the earth. Perhaps it may be unable to support so large a population as now, and perhaps fewer will desire to live on it. On the other hand, mankind, being three million times as old as now, may—if the conjecture does not distress our pessimists too much—be three million times as wise.

Looked at on the astronomical time-scale, humanity is at the very beginning of its existence—a new-born babe, with all the unexplored potentialities of babyhood; and until the last few moments its interest has been centred, absolutely and exclusively, on its cradle and feeding-bottle. It has just become conscious of the vast world existing outside itself and its cradle; it is learning to focus its eyes on distant objects, and its awakening brain is beginning to wonder, in a vague, dreamy way, what they are and what purpose they serve. Its interest in this external world is not much developed yet, so that the main part of its faculties is still engrossed with the cradle and feeding-bottle, but a little corner of its brain is beginning to wonder.

Taking a very gloomy view of the future of the human race, let us suppose that it can only expect to survive for two thousand million years longer, a period about equal to the past age of the earth. Then, regarded as a being destined to live for threescore years and ten, humanity, although it has been born in a house seventy years old, is itself only three days old. But only in the last few minutes has it become conscious that the whole world does not centre round its cradle and its trappings, and only in the last few ticks of the clock has any adequate conception of the size of the external world dawned upon it. For our clock does not tick seconds, but years; its minutes are the lives of men. A minute and a half ago the distance of a star was first measured and provided a measuring-rod for the universe. Ten seconds ago Shapley showed how the peculiar stars known as Cepheid variables provide a longer measuring-rod, and taught us to think in distances so great that light takes hundreds of thousands of years to traverse them. With the very last tick of the clock, Hubble, using the same measuring-rod, has found that the most remote objects visible in the biggest telescope on earth are so distant that light, travelling 186,000 miles a second, takes about 140 million years to come from them to us.

---

[1] The Trueman Wood Lecture delivered before the Royal Society of Arts on Wednesday, Mar. 7.

Not only is our vision of the universe continually expanding, but also it is expanding at an ever-increasing rate. Is this expansion destined to go on for ever ? So far as we can at present see, no ; for a general guiding principle, that of generalised relativity, fixes a limit, which we are fast approaching. According to this theory, space cannot extend for ever ; it has no limit, but is nevertheless finite like the surface of the earth. Without exploring and surveying the whole of the earth's surface, we can make a fair estimate of its total area by measuring its radius, which we can do by measuring its curvature at any one point. In the same way the total volume of space is fixed by a quantity, the curvature of space, which can be determined by measuring the density of distribution of matter in space. Space which contained no matter would go on for ever, but the parts of space we can survey with our telescopes contain enough matter to show that we already see an appreciable fraction of the whole of space. It is as though our baby, watching ships coming from over the horizon, concluded that the earth's surface was curved, and formed a general rough conception of its size by imagining the observed curvature continuing until the earth's surface rounded back on itself.

Exact figures are impossible, but Hubble has calculated that space is not likely to extend to more than about a thousand times as far as the farthest nebula visible in the biggest telescope. Nothing prevents our going on and on in space beyond this distance, but, if we do, we merely come back to ourselves. The possessor of a sufficiently sensitive wireless apparatus may emit signals and pick them up a seventh of a second later after they have travelled round the world. In the same way a not inconceivable increase in the size of our telescopes would take us round the whole of space, and we should see the stars surrounding our sun by light which had travelled round the universe, not of course as they now are, but as they were 100,000 million years ago.

Such considerations make it improbable that the expansion of the universe can continue at its present rate for much longer. Having grasped that the world is round, the infant speedily forms a fair idea of its size. Our particular infant, mankind, has made the great discovery of the existence of the outer world, has formed some conception of its size, and adjusted his ideas, not by a process of slow revelation, but by a brain-flash of the last few seconds. In his mature years and his staid old age he is no doubt destined to make many sensational discoveries, but he can never again live through the immortal moment at which he first grasped the immensity of the outer world. We only live through a few ticks of his clock, and fate might have ordained that they should be anywhere in the three days that the child has already lived, or in the seventy long, and possibly tedious, years yet to come. The wonderful thing is that she has selected for us what is, perhaps, in some ways the most sensational moment of all in the life of our race.

The child sets its newly awakened mind to work to adjust and co-ordinate a new array of facts. If the world was not made to surround its cradle, what purpose can it serve ? If the lights of the great ships in the harbour were not designed to light its nursery at night, what can they possibly be for ? And, most interesting problem of all, if the world is such a big affair, can there be other cradles and other babies ?

These remarks will have served their purpose if they suggest that what I am rashly trying to set forth here should not be judged as a finished science or the solution of a problem ; it is rather the first confused gropings of the infant mind trying to understand the world outside its cradle. And if the impression produced by its first inexperienced glance at the outer world had to be described in a single word, it would probably select the word 'immensity.'

The Immensity of Space.

The immensity of space is measured by the figures already mentioned. Light and wireless signals travel at the same rate because, of course, they are essentially the same thing ; and this thing takes a seventh of a second to travel round the world, and probably something like 100,000 million years to travel round the universe. The ratio of these times (2×10^{19}) measures the dimensions of the universe in terms of the familiar dimensions of the world ; incidentally, it also measures the expansion of our spatial ideas since Copernicus. The disparity of size is too great to be easily visualised. Suppose the size of our earth represented by a single atom. Then the range of vision of the biggest telescope is about represented by the whole earth, and the size of the whole universe, according to the theory of relativity, is represented by a stack of a thousand million earths.

Scarcely less bewildering than the immense extent of space is the immense amount and variety of matter it contains. The sun, which is a million times as big as the earth and 300,000 times as massive, proves to be something less than a grain of sand on the seashore. It forms one of a family whose number must certainly be counted in thousands of millions; Seares has estimated it at thirty thousand millions. This is not the only family of stars in space. Each of the great spiral and other extra-galactic nebulæ, such as are shown in Figs. 1, 2, and 3, is either a family of stars, or consists of stars in the making, or of matter which is destined ultimately to form stars. We can estimate the masses of these great nebulæ by gravitational means, and each is found to contain enough matter to make a thousand million suns. This of itself will give some conception of the vast size of these nebulæ, but to tell the whole story, it must be added that their colossal masses are so tenuous that each millionth part of an ounce is, on the average, as big as the Matterhorn. Think of a body which is bigger than the Matterhorn by as much as a thousand million suns is heavier than a millionth part of an ounce, and we have the size of any one of these great nebulæ. Any one of the three photographs here reproduced would have to be enlarged so as to cover the whole of Asia before a body of the size of the earth became visible in it at all, even under the most powerful of microscopes.

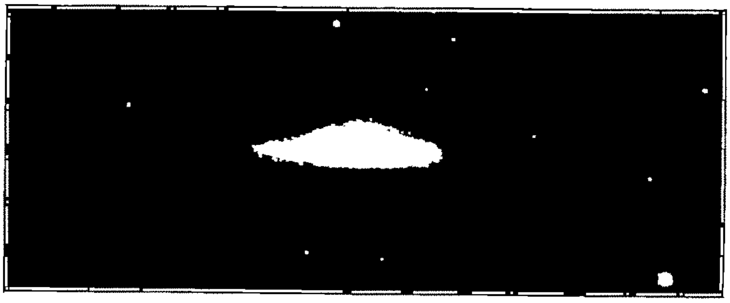

FIG 1.—Regular shaped nebula (N G C 4594) with ring of dark matter surrounding equator.

Hubble estimates that about two million such nebulæ are visible in the great 100-inch telescope at Mount Wilson, and that the whole universe has about a thousand million times the volume of that part of space visible in this telescope. Let us now multiply 1000 million by 2 million, and the product by 1000 million. The answer (2×10^{24}) gives some indication of the probable number of stars in the universe; the same number of grains of sand spread over England would make a layer hundreds of yards in depth. Let us reflect that our earth is one millionth part of one such grain of sand, and our mundane affairs, our troubles and our achievements, begin to appear in their correct proportion to the universe as a whole.

While the stars may fairly be compared to grains of sand in number, they differ too much *inter se* for the comparison to be carried further. There is an enormous variety of big and little stars, of bright and faint stars, of red and blue stars, and of hot, hotter, and still hotter stars. The faintest of known stars (Wolf 359) emits only a fifty thousandth part of the light of the sun, while the brightest (S. Doradus) emits 300,000 times as much light as the sun. The smallest known star (Van Maanen's star) is about the size of the earth; a million such stars could be packed inside the sun and leave room to spare. The largest known star (Betelgeuse) is so large that 25 million suns could be packed inside it. Their ranges are greater than those between a searchlight and a glowworm, or between balloons and bird-shot.

Yet the stars are essentially similar structures. A normal atom consists of a central nucleus round which a number of electrons revolve like planets round the sun—a miniature solar system, in fact, in which the vacant space far exceeds that occupied by matter. With great heat the electrons begin to break loose and fly off at a tangent. The central temperatures of the stars can be calculated with fair precision, and prove to be so high that most of the electrons must have already broken loose from their atoms. Of recent years, a great deal of labour has been devoted to testing the hypothesis that practically all the electrons have so broken loose, the stripped atoms and electrons flying about in a general hurly-burly like the molecules of a gas. But the hypothesis has proved disappointing, and a much more probable hypothesis is, I think, that the atoms are not stripped quite bare, but that in most stars they retain a few rings of electrons which give the atoms so much size that they jostle one another about like the molecules of a liquid. This hypothesis explains beautifully the otherwise puzzling fact that stars of large mass fall into distinct groups, of what may almost be described as 'standardised' sizes. On the 'liquid star' hypothesis, these different sizes correspond to the different sizes possible for the stellar atoms, which may have 0, 1, 2, or 3 rings of electrons left, but cannot have fractional numbers. The largest stars of all, such as Betelgeuse, have three rings left, while minute stars, such as Van Maanen's star, consist of atoms most of which are stripped quite bare, so that there is almost no limit to the closeness with which they can be packed together. An average handful of the matter of which this star is composed would contain about ten tons.

Thus the observed sizes of the stars proclaim the secret of the structure of the atom. The sizes of the stars are discontinuous because the sizes of atoms broken down to different stages are discontinuous. These discontinuities can be traced in turn to the discontinuities which form the central feature of the new quantum dynamics Thus the distinguishing characteristic of the laws which govern the most minute processes in Nature is transmitted directly into the large scale phenomena of astronomy and governs the distribution of the huge masses of the stars. The infinitely great is never very far from the infinitely small in science, but it would be hard to find a more sensational illustration of the unity of science than that I have just given.

On this hypothesis, not only do the observed sizes of the stars disclose the general structure of the atom, which is old knowledge, but they also reveal the detailed structure of the particular atoms of which the stars are composed, and this is new knowledge. To be precise, the observed sizes of the stars disclose the atomic weights of the stellar atoms; they indicate that the stellar atoms are probably rather heavier than the heaviest atom, uranium, known on earth. The atoms which reveal their presence in stellar spectra are, of course, atoms of the ordinary terrestrial elements—hydrogen, iron, calcium, and the like. These, being the lightest atoms in the star, must naturally float up to its surface, and, as the earth was originally formed out of the surface of the sun, the earth is necessarily composed of them. But it now appears likely that down in the depths of the stars are other unknown and heavier atoms. We may almost say that it must be so, for no terrestrial atoms, not even radium or uranium, can produce anything like the amount of energy which these stellar atoms are observed to produce.

THE IMMENSITY OF TIME.

The immensity of space is paralleled by that of time. We can estimate the ages of stars from the impression that time has made upon them, just as we estimate the age of a tree from the number of subdivisions of its stem, or of rings in its cross section There are three principal methods of doing this. The orbits of binary stars, which are circular at birth, are gradually knocked out of shape by the forces from passing stars. As we can calculate the rate at which this process occurs, the shape of stars' orbits can be made to reveal their ages. The moving clusters provide a second method. Groups of bright stars such as the Great Bear, the Pleiades, Orion's Belt, are often found to consist of exceptionally massive stars which move in regular orderly formation through a jumble of slighter stars, like a flight of swans through a confused crowd of rooks and starlings. Swans, however, are conscious beings, and continually adjust their flight so as to preserve their formation. The swan-like stars cannot do this, so that their orderly formation must in time be broken by the gravitational pull of other stars. When this happens, the lighter stars are naturally knocked out of formation first, while the most massive stars retain their formation longest. This agrees with what is observed, and as we can calculate the time necessary to knock out the lighter stars, we can at once deduce the ages of those which are left in. A third method of investigation rests upon a rather abstruse dynamical theorem, which shows that after a sufficient time the energies of motion of the different types of stars must tend to equality, the little stars making up for the smallness of their mass by the rapidity of their motion. Seares has shown that the stars near the sun have nearly attained to this ideal state, and as we can calculate the time needed to establish it, we can again deduce the ages of the stars.

It is gratifying and significant that all three lines of investigation lead to the same result: the stars are found to be some millions of millions of years old, perhaps from five to ten millions of millions. We cannot state their age with much precision, but it is the general order of magnitude, not the exact figure, that is important.

STELLAR RADIATION.

Year after year, century after century, for millions of millions of years, the sun radiates enough energy from each square inch of its surface to keep a 50 h.p. engine continually in action; still hotter stars may radiate as much as 30,000 h.p. per square inch. If this energy were produced by the combustion of coal, the stars would all be completely burnt out in a few hundreds or thousands of years. Where, then, shall we find a source of energy to last millions of millions of years?

More than twenty years ago I directed attention to the enormous store of energy made available by the annihilation of matter, by positive and negative electrons falling into and annihilating one another, thus setting free the whole of their intrinsic energy as radiation. On this scheme neither energy nor matter had a permanent existence, but only a sort of sum of the two ; each was, theoretically at least, convertible into the other. Whether energy is ever transformed into matter we do not know ; probably not. But the falling together of electrons and protons forms the obvious mechanism for the transformation of matter into energy, and it now seems practically certain that this is the actual source of the radiation of the stars. A beam of radiation exerts pressure on any surface it falls upon, just as a jet of water does or a blast of air. The reason is that radiation carries mass about with it, and electromagnetic theory tells us the amount of this mass. For example, we can calculate that a searchlight which is radiating 50 horse-power of energy is discharging mass into space with the radiation at the rate of a gramme and a quarter a century ; with sufficiently delicate adjustments it might even be possible to observe the recoil of the searchlight. Indeed, the pressure of radiation has actually been measured, although not in this particular way. New mass is of course being continually fed into the searchlight by the electric current.

Each square inch of the sun's surface is in effect a searchlight discharging radiation into space at the rate of 50 horse-power, and so is discharging mass at the rate of a gramme and a quarter a century, and the sun's surface is so large that the sun as a whole is discharging mass into space at the rate of 250 million tons a minute Now the sun has no source of replenishment. It must have weighed 360,000 million tons more yesterday than to-day, and by to-morrow will weigh 360,000 million tons less. These are not mere speculative statements ; they rest on observation, and on generally accepted principles which are directly confirmed by observation.

Allowing for the fact that a more massive star emits more radiation than a less massive one, we can calculate that five or ten million million years ago the sun must have been several times as massive as it is to-day, so that it has already lost most of the mass it had at birth. Of each ton it had at birth only a few hundredweights at most remain to-day. The loss of mass which accompanies radiation is, then, no mere academic hair-splitting. It is a real astronomical phenomenon, and young stars must be many times as massive as old stars.

There is a certain amount of direct evidence of this change of mass. The radiation of the stars imposes an endlessly recurring capital levy upon their masses, which, as observation shows, is graduated and increases very steeply indeed for the richest stars. The levy makes all the stars poorer, but it also tends to equalise what wealth remains ; the older the stars get, the more nearly equal their impoverished masses become. This is a large part of the reason why the stars are nearly equal in mass. The process is most clearly marked in the binary systems, which have been formed by a single star breaking into two. The two component stars of such a system are necessarily of the same age, and it is a matter of observation that the small stars of old systems are nearer to equality of mass than the massive stars of young systems.

Thus observation and theory agree in indicating that the universe is melting away into radiation. Our position is that of polar bears on an iceberg that has broken loose from the icepack surrounding the pole, and is inexorably melting away as the iceberg drifts to warmer latitudes and ultimate extinction.

Five million million years ago the sun had stored up within itself the energy which was destined to provide its light and heat until to-day, and the mass of this energy was many times the present mass of the sun. No means is known by which so much mass could be stored except in the form of electrons and protons. Thus we must suppose that the radiation of the sun through these millions of millions of years has been produced by the annihilation of electrons and protons which existed in it originally, but no longer exist now. These electrons and protons are pure bottled energy ; the continuous breakage of these bottles in the sun sets free the radiation which warms and lights our earth, and enough unbroken bottles remain to provide light and heat for millions of millions of years to come.

The amount of energy made available in this way is amazing. The annihilation of a pound of coal a week would produce as much energy as the combustion of the five million tons a week which are mined in the British Isles ; an ounce of coal a month would provide locomotive power for all the British railways, while a single drop of oil would take the ***Mauretania*** across the Atlantic. When we speak of the efficiency of a steam engine as 5 per cent. or so, we regard complete use of the thermal energy of combustion as 100 per cent. efficiency. If we measure the work done against the total intrinsic energy of the fuel, as made available by its complete annihilation, the efficiency is more like 0·00000001 per cent. On this scale the efficiency of the sun and stars is exactly 100·00 per cent.

Modern physical theory shows that the annihilation of an electron must produce a single flash of radiation of wave-length far shorter than any we can produce on earth. As this radiation threads its way through a star, its wave-length is continually increased, or, to use the technical term, the radiation is continually softened. In time it becomes γ-radiation, then hard X-radiation, then soft X-radiation, and finally it emerges from the surface of the star as ordinary light and heat. Consider, however, an electron which is annihilated not inside a star but outside in free space, or in one of the almost transparent nebulæ. The short wave-length radiation now undergoes no softening, but travels on until it meets something capable of checking it. Thus all astronomical bodies, including the surface of the earth, ought to be under continual bombardment by radiation of shorter wave-length, and consequently of greater penetrating powers, than any we can produce on earth.

Many years ago such radiation was detected in the earth's atmosphere by McLennan, Rutherford, and other observers; it has recently been studied in detail by Millikan and others. There is no reason to doubt that it originates just where it ought to, namely, in the great nebulæ, and its amount is about what it ought to be, if it is evidence of the whole universe melting away into radiation. The wave-length of the radiation might be expected to reveal the physical process by which it is generated, but the evidence is a bit puzzling. The hardest terrestrial radiation penetrates inches of lead and corresponds to a voltage of hundreds of thousands of volts. The cosmic radiation penetrates about five yards of lead, and the hardest rays are now found to correspond to about 60 million volts. Millikan was at one time inclined to attribute the rays to the combination of four atoms of hydrogen to form an atom of helium, but rays so produced would only be of the hardness corresponding to 30 million volts. There are many ways known to physics of softening radiation, but none of hardening it. Thus we must look for some source more energetic than the synthesis of hydrogen into helium, and I can see no possible stopping-place short of the annihilation of matter. Again, we are not dealing with a minute phenomenon of mere academic interest. In a sense this radiation is the most fundamental physical phenomenon of the whole universe, most regions of space containing more of it than of visible light or heat. Our bodies are traversed by it night and day. Short of going down into a mine or in a submarine we cannot escape it, and it is so intense that it breaks up several million atoms in each of our bodies every second. It may be essential to life or it may be killing us.

The Lives of the Stars.

The stars are almost certainly born in nebulæ of the type of the great extra-galactic nebulæ, such as are shown in Figs. 1, 2, and 3. These nebulæ show a great variety of shapes, but a single thread connects them all; they are the shapes of huge masses of gas endowed with different amounts of rotation. So definitely is this the case that when Hubble recently tried to classify the shapes of these nebulæ, deliberately and avowedly shutting his eyes to all theoretical considerations, he found that purely observational considerations compelled him to classify them in precisely the sequence I had predicted on theoretical grounds some ten years earlier.

A huge mass of gas which was entirely devoid of rotation would of course assume a strictly spherical shape; rotation would flatten this shape out, just as the earth is flattened by its rotation, until ultimately most of the matter was spread out in a thin disc. We see the process beginning in Fig. 1, and it is well advanced in Fig. 2. Fig. 3 shows a nebula which is probably physically similar to that shown in Fig. 2, but viewed from another angle. Now mathematical theory shows that the thin disc-like structure could not remain a mere featureless mass of gas. Just as the cooling of a cloud of steam causes it to condense into drops of water, so the cooling of a cloud of gas causes it to condense into detached masses. We see the phenomenon in progress in nebular photographs; it is a necessary theoretical consequence of the laws of gases and the law of gravitation.

Now the same theory which predicts that the phenomenon must happen, predicts the scale on which it will happen. We can calculate how much matter will go to the formation of each 'drop,' and the calculated masses of the drops come out to be just about the same as the masses of the stars. Indeed these drops are stars, and the process just described is that of the birth of stars. Unmistakable stars have been observed in the outer regions of many of the spiral nebulæ. It is naturally not possible to identify every observed spot of light with a star, but some of them show precisely the same peculiar fluctuations of light as characterise a certain class of variable star, the Cepheid variables already mentioned, and these put the identity of these particular spots of light beyond all reasonable doubt.

In these nebulæ, then, we are watching the birth of stars, the transformation of an inchoate mass of gas into an 'island universe' of stars. Indeed Hubble found it necessary to end up his classification of nebulæ with clouds of stars. At one end of his continuous sequence is a nebula, shaped like a mass of rotating gas, in which not a single star is visible: at the other end a star-cloud in which nothing but stars are visible. Our galactic system of stars is probably the final product of just such a transformation, the Milky Way still recording the position of the equatorial plane of the original nebula.

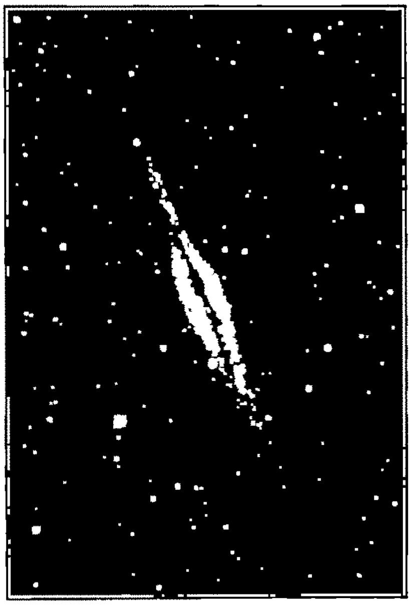

FIG. 2 —Spiral nebula (N.G.C. 891) seen edge on.

Stars born in this way may meet with a variety of accidents and these result in different observed astronomical formations. A star may rotate too fast for safety, just as a flywheel may; when this happens it breaks into two, and the two stars so formed revolve endlessly about one another as a binary system. Two stars may run into one another, although this is very rare. A more common occurrence is for two stars to escape running into one another by a narrow shave. When this happens, huge tides are raised on the two stars involved, and these may take the form of long streamers of gas, which ultimately condense into 'drops' just as did the gas in the outlying regions of the spiral nebulæ. It seems reasonably certain that the planets were formed in this way.

The birth of the solar system, then, resulted from the close approach of two stars; if a second star had not happened to come close to our sun, there would have been no solar system. It may be thought that with a life of millions of millions of years behind it, one star or another would have been certain to come near enough at some time to tear planets out of the body of our sun. Calculation shows the reverse; even after their long lives of millions of millions of years, only about one star in 100,000 can be surrounded by planets born in this way. A quite unusual accident is necessary to produce planets, and our sun with its family of attendant planets is rather of the nature of an astronomical freak.

In the thousand million stars surrounding our sun there are, at a moderate computation, not more than ten thousand planetary systems, because there has not been time for more than this number to be born. They are of course still coming into existence; calculation suggests a birth-rate of about one per thousand million years. Thus we should have to visit thousands of millions of stars before finding a planetary system of as recent creation as our own, and we should have to visit millions of millions of stars before finding a planet on which civilisation, and interest in the outer universe, were

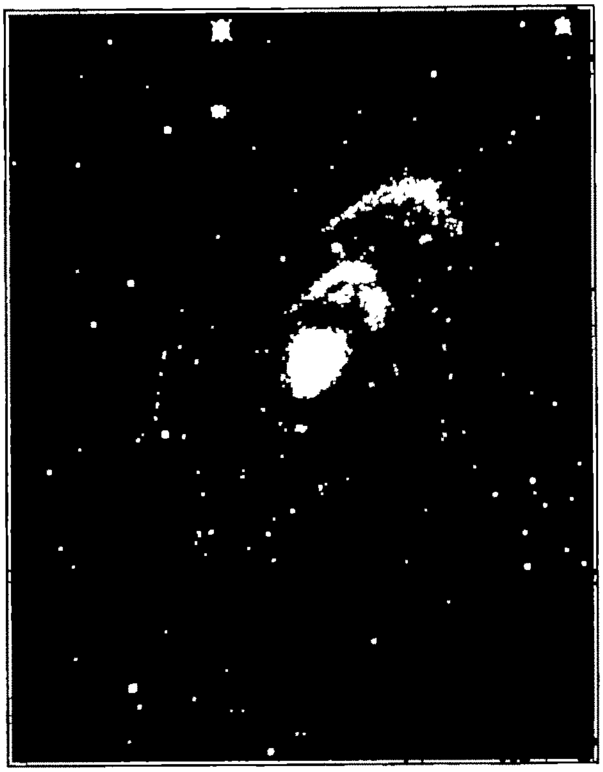

FIG 3.—Spiral nebula in Ursa Major (M. 81).

as recent a growth as are our own. We are standing at the first flush of the dawn of civilisation, and are terribly inexperienced beings.

It may be suggested that the creation of planetary systems is also only beginning, and that in time every star will be surrounded, like our sun, by a family of planets. But no; the stars will have dissolved into radiation or disappeared into darkness before there is time for this to happen. So far as we can judge, our part of the universe has lived the more eventful part of its life already; what we are witnessing is less the rising of the curtain before the play than the burning out of candle-ends on an empty stage on which the drama is already over. There is not time for many more planets to be born.

LIFE AND THE UNIVERSE.

The planets are the only places we know where life can exist. The stars are too hot; even their atoms are broken up by the intense heat. Nebulæ are in every way unsuitable; even if cool solid bodies exist in them, they would probably be so drenched with highly penetrating radiation as to render life impossible. Life demands a special type of matter, such as does not produce intense light and heat by transforming itself into radiation. We find it only in the surfaces of the stars, which are too hot for life; and in the planets which have been pulled out of these surfaces.

On any scheme of cosmogony, life must be limited to an exceedingly small corner of the universe. To our baby's wonderings whether other cradles and other babies exist, the answer appears to be that there can at best be very few cradles, and there is no conceivable means of knowing whether they are tenanted by babies or not. We look out and see a universe consisting primarily of matter which is transforming itself into radiation, and producing so much heat, light, and highly penetrating radiation as to make life impossible. In rare instances, special accidents may produce bodies such as our earth, formed of a special cool ash which no longer produces radiation, and here life may be possible. But it does not at present look as though Nature had designed the universe primarily for life; the normal star and the normal nebula have nothing to do with life except making it impossible. Life is the end of a chain of by-products; it seems to be the accident, and torrential deluges of life-destroying radiation the essential.

There is a temptation to base wide-reaching inferences on the fact that the universe as a whole is apparently antagonistic to life. Other quite different inferences might be based on the fact of our earth being singularly well-adapted to life. We shall, I think, do well to avoid both. Each oak in a forest produces many thousands of acorns, of which only one succeeds in germinating and becoming an oak. The successful acorn, contemplating myriads of acorns lying crushed, rotten, or dead on the ground, might argue that the forest must be inimical to the growth of oaks, or might reason that nothing but the intervention of a special providence could account for its own success in the face of so many failures. We must beware of both types of hasty inference.

In any case, our three-days-old infant cannot be very confident of any interpretation it puts on a universe which it only discovered a minute or two ago. We have said it has seventy years of life before it, but in truth its expectation of life would seem to be nearer to 70,000 years. It may be puzzled, distressed, and often irritated at the apparent meaninglessness and incomprehensibility of the world to which it has suddenly wakened up. But it is still very young; it might travel half the world over before finding another baby as young and inexperienced as itself. It has before it time enough and to spare in which it may understand everything. Sooner or later the pieces of the puzzle must begin to fit together, although it may reasonably be doubted whether the whole picture can ever be comprehensible to one small, and apparently quite insignificant, part of the picture. And ever the old question obtrudes itself as to whether the infant has any means of knowing that it is not dreaming all the time. The picture it sees may be merely a creation of its own mind, in which nothing really exists except itself; the universe which we study with such care may be a dream, and we brain-cells in the mind of the dreamer.

Printed in Great Britain by R. & R. CLARK, LIMITED, Edinburgh.

and procedure of the survey. News of the actual work and results of this very interesting development in the application of research to Imperial problems will be awaited with keen interest.

THE freedom of the City of Stoke-on-Trent was conferred, on Mar. 14, on Sir Oliver Lodge, who was born at Stoke in 1851. Lady Lodge, who accompanied her husband, has local associations too, and Sir Richard Lodge, formerly professor of history at the University of Edinburgh, accompanied his brother. The visitors were heartily welcomed throughout their brief stay, and at Stoke Town Hall were received by the Mayor, Alderman T. C. Wild. Among others, the city electrical engineer, Mr. C. H. Yeaman, was introduced to Sir Oliver, under whom he studied at Liverpool. Sir Oliver and Lady Lodge were greeted enthusiastically by the aldermen, councillors, and citizens assembled in the Council Chamber. The Mayor, in moving the resolution to admit Sir Oliver as an honorary freeman, referred to his attainments and his important contributions to the striking progress made in modern times, concluding by offering, on behalf of the Council and the inhabitants of his native city, "a very hearty and sincere welcome home." The Deputy-Mayor seconded, and the motion was carried with great applause, the Mayor then handing to Sir Oliver the freeman's scroll. Sir Oliver Lodge, responding, recalled that thirty years ago, when he received the Rumford Medal of the Royal Society, he regarded it as the highest honour of his life. Now he doubted it, for few people receive the freedom of their native city, especially after more than fifty years' absence. Continuing in reminiscent mood, Sir Oliver mentioned, *inter alia*, that he left school at fourteen years of age, then for seven years was his father's book-keeper, devoted all spare time to such pursuits as mathematics, physics, and experiments, attended local science classes, and eventually got to University College, London, for further study.

THE Bodleian Library, Oxford, contains at present about 1,500,000 volumes, besides more than 40,000 manuscripts. To this collection between 20,000 and 25,000 volumes are added each year. At the present rate of growth the existing accommodation will not last more than another eight or nine years. To meet the need which will soon become pressing, various measures have been suggested, the most important of which are the following: (*a*) To build an extension of the Bodleian Library on the north side of Broad Street, and to acquire sufficient land in the neighbourhood of Oxford to provide accommodation for little-wanted books and periodicals. It is estimated that this plan would give the necessary space for at least 100 years. (*b*) To build an entirely new library in a central place, keeping Duke Humfrey's fifteenth century Library with the Arts and Selden ends as a library of early printed books, and the Radcliffe Camera as a reading-room for undergraduates. The cost of a new building such as is contemplated would be about £500,000. It is obvious that the expense of either plan could only be met by a great benefaction. Advocates of the second plan consider that it would remedy certain admitted inconveniences in the present administration of the Library. In particular, they allege the unavoidable slowness in book-service, the restricted hours of opening, the limitation of access to the shelves by readers. It is, however, not admitted by the supporters of the former plan that these drawbacks could not be remedied under the alternative scheme, if sufficient funds were forthcoming. In either event, a revision of the catalogue, estimated to cost £100,000, is considered to be highly desirable. It is not proposed that under either scheme the Radcliffe Scientific Library, now a department of the Bodleian, should be moved from the Museum.

IN order to commemorate the work of that great educationist, the late Dr. A. H. Fison, Guy's Hospital Medical School and the Gilchrist Trustees founded the Fison Memorial Lectureship four years ago. The first lecture on "The Structure of Light" was given by Sir J. J. Thomson, and the second by the Very Reverend Dr. W. R. Inge on "Science and Ultimate Truth." The third lecture was delivered by Sir William Bragg on Mar. 13, at Guy's Hospital Medical School, under the chairmanship of Sir William Pope. In his introduction, Sir William Bragg described "The Structure of an Organic Crystal" as a "borderline subject in that it draws from physics the explanation of the new methods by which the structure is found; it relies on chemistry for valuable comparisons between its own determinations and the picture of the organic molecule which the older science is able to supply; and it looks forward to a fruitful connexion with the biological sciences in which the organic molecule plays so great a part."

SIR WILLIAM BRAGG's lecture was both a record of achievement and a statement of unsolved problems. X-ray analysis, which has shown on one hand that the structural formulæ of organic compounds are plans rather than diagrams, and has enabled the lattice constants of crystals to be measured with high accuracy, has still advanced insufficiently to permit of full interpretation of the diffraction pattern of such a relatively simple substance as naphthalene. It has shown that there is a definite structure in the normal aliphatic carbon chain, but cannot explain satisfactorily why even numbered chains occur more frequently in Nature than the odd members, and although it has proved that many bodies which were supposed at one time to be amorphous are really essentially crystalline, it still leaves as a curious fact that complicated molecules often produce a simple unit of pattern in the aggregate. A point stressed by Sir William in his concluding remarks was that, interesting and significant as the new results are in relation to molecular structure, biologically they are literally of vital importance. The lecture has been published by Messrs. Longmans, Green and Co., Ltd. (1/6 net).

IN his Friday evening discourse at the Royal Institution on Mar. 16, Prof. E. T. Whittaker discussed "The Quantum and Relativity Theories of Light." He stated that the classical theory of light, created by Fresnel in 1816–23, and transformed into an electromagnetic theory by Maxwell in 1861–62, was believed at the end of the nineteenth century to be capable of accounting for all optical phenomena. Since then, a number of facts have been observed which appear to be irreconcilable with it, for example, the photo-electric effect; and a great and successful theory—the quantum theory of spectra—has been developed, which presents a picture of radiation quite different from that given by the electromagnetic theory of light. Dealing first with the last-named difficulty, Prof. Whittaker showed that it has been almost completely removed by the new wave-mechanics. In place of the 'stationary states' of the old quantum theory, which were interpreted as the description of particular orbits by electrons, we now have normal solutions of the wave-equation. In a normal solution, the electric moment of the atom does not vary with the time, and there is therefore no reason why, in the electromagnetic theory, radiation should be emitted. On the other hand, when the state of the atom is represented by a superposition of two normal solutions, the electric moment does vary with the time, and radiation is emitted until the atom arrives at a state represented by a single normal solution. Prof. Whittaker then discussed the difficulties raised by the photo-electric effect, and showed that the classical theory is not in contradiction with the capture by a single atom of a whole quantum of radiation, or the preservation of the identity of the quantum as it travels over great distances. The latter part of the lecture was devoted to the new theory of the five-dimensional universe and to the behaviour of light rays in a gravitational field according to the theory of general relativity. It is found that a light ray may be captured permanently by the gravitational field of a point-mass.

On Monday, Mar. 19, at the Æolian Hall, a paper entitled "From the White Nile to Ruanda" was read before the Royal Geographical Society by Mrs. Patrick Ness, describing part of a journey through Africa from Cairo to Cape Town, planned and carried out by her in the winter of 1926–27, with impressions gained at different times before 1914, when accompanying her late husband on big-game shooting expeditions. The regions principally dealt with were the little known lands in the extreme south-west of Uganda; the volcano lands of the Mufumbiro Mountains in the heart of Africa; Lake Kivu and the interesting kingdom of Ruanda, which with Urundi is now mandated territory administered by Belgium under the League of Nations. The paper gave a picture not only of these beautiful equatorial uplands, but also of the various tribes met with, often curiously different though inhabiting the same localities, and again in some cases resembling each other in many ways though found hundreds of miles apart. To-day, when Africa is so opened up that motors can be driven from end to end, there still remain parts into which no car has penetrated, and on the route described from Uganda to the Belgian Congo, which climbs to more than 8000 feet, all loads are still carried on men's heads.

We learn from a recent *Daily News Bulletin*, issued by Science Service of Washington, that the General Electric Company of America has made a vacuum tube which, when connected to a copper bar about ten feet long through a coupling system, acts as a tuned aerial circuit. The tube is five inches in diameter and is two feet long. The power taken is 15 kilowatts and the great bulk of this is radiated into space with a frequency of 50,000 kilocycles, that is, the radio waves have a length of only six metres. With such short waves, many curious phenomena are noticed in the neighbourhood of the copper bar. If one terminal of an ordinary electric lamp be put in contact with the copper bar, it lights up brilliantly. When a piece of copper lying on the floor is picked up, the fingers may be blistered although it appears cold. Doubtless the induced currents at this high frequency are all confined to a very thin outside layer of the metal. Cooking can be carried on inside a glass tube near the aerial. The waves also affect everyone who approaches too close to the copper bar; a warm glow all over is first felt, and then pains ensue in the limbs and joints. It is stated that after standing close to the aerial for fifteen minutes the body temperature is raised to 100° F., and thus an artificial fever has been induced. Dr. Whitney, the director of the G.E.C. Research Laboratory, says that if we had a perfectly harmless method of warming the blood, it might be of value to the medical profession. An apple placed on the end of a wire at some distance from the aerial was thoroughly baked in a few minutes. When the end of the aerial was touched with a metal tipped rod, a greenish-white arc arose at the point of contact to a height of about a foot. As many as three of these standing arcs, each without any visible return circuit, could be established simultaneously, each flame spluttering and sending out molten copper in all directions until it was blown out.

Sir John Russell, Director of the Rothamsted Experimental Station, will shortly leave England to visit Australia, where he is going at the invitation of the Australian universities to lecture on the applications of science to agriculture, especially to crop production, showing what science has done and is doing to assist the farmer. While there he will, at the invitation of the Commonwealth Council of Scientific and Industrial Research, visit some of the more important developments and soil reclamation schemes in progress, and discuss the problems with the Australian experts on the spot. He will also visit the chief centres of agricultural investigation, and among other things will discuss the possibility of exchange of information and rendering of mutual assistance between the British and the Australian agricultural investigators.

The first dynamo test in the world was made in the winter and spring of 1878, in the hall of the Franklin Institute of Philadelphia, by Dr. Elihu Thomson and Prof. E. J. Houston. The tests were carried out on various types of dynamos in order to determine which was the most efficient. As a result of these tests, a Brush arc light generator was recommended for purchase by the Franklin Institute. A celebration of the semi-centennial of these tests will be held in the Franklin Institute on the afternoon of Wednesday, April 18, in the hall of the Institute, when papers will be presented by Dr. Elihu Thomson, the survivor of the two who made the tests, and by Dr. Charles F. Brush, who invented the type of dynamo finally recommended. It is expected that representatives of the great electrical companies of the United States and Canada, as well as many scientific workers of these two countries, will be present to participate in this celebration. All scientific workers and members of scientific organisations of Europe who may be in the United States at that time will be heartily welcomed by the Franklin Institute.

ON Mar. 14 the Frank N. Meyer Medal for distinguished service in plant introduction was presented to Mr. H. N. Ridley, in recognition of the important part he played in establishing plantations of the Para rubber tree in the Oriental tropics. The presentation was made by the American Consul General on behalf of Mr. David Fairchild, president of the American Genetic Association, to whom the award is entrusted by the staff of the Office of Foreign Plant Introduction, United States Department of Agriculture. Mr. H. L. Washington, in presenting the medal, referred briefly to the pioneer work carried out by Mr. Ridley whilst Director of the Botanic Gardens, Straits Settlements, in securing seed of the Para rubber tree from the trees growing at Singapore, in order to start the plantations in Malay; to his work in raising improved kinds of the tree by selection, and to his early experiments in tapping. Appreciative references were also made to the part played by the Royal Botanic Gardens, Kew, in the original introduction of this tree from South America to the Far East.

J. P. AULT, commander of the yacht *Carnegie*, has contributed an interesting review of magnetic ocean surveys to the February number of the *Scientific Monthly*. Columbus is credited with the discovery of the magnetic variations of the compass; when seven days out from the Canaries, during his first voyage to America in 1492, he found that the compass needles had turned to the north-west of north, and on the following morning further to the north-west. Two hundred years later, substantial prizes were offered for improvements in navigational methods, and Edmund Halley, the astronomer, began his voyages in the *Paramour* "to improve the knowledge of the longitude and variations of the compass." As a result, he constructed and published the first magnetic chart of the oceans, his method of drawing lines through points of equal magnetic variation being still used on modern charts. During the two hundred years which have elapsed since Halley's voyages gross changes have taken place in the magnetic field. In London the compass needle pointed 11° east of north in 1580, in 1812 it was pointing 24° west of north, and it now points about 13° west of north. The causes of these changes are unknown; their explanation and the determination of the rates of change constitute one of the chief problems in terrestrial magnetism. The Carnegie Institution of Washington equipped and sent out the non-magnetic ship *Galilee* to the Pacific, to be followed by the yacht *Carnegie*, which has already sailed some 290,000 sea miles. It is proposed to sail on a seventh cruise in May next. Besides continuing the magnetic survey, it is proposed to carry out a series of determinations of the potential gradient of the atmosphere immediately above the sea, and to prosecute a carefully prepared programme of oceanographic research. By finding the density *in situ* of the water at various depths down to 2000 metres every hundred miles or so, it will be possible to arrive, by means of Bjerknes' circulation theory, at the components at right angles to the track of the voyage of the velocities of the various water layers, relative to each other. It is also proposed to make a survey of the phosphate content of the ocean waters, a matter of particular interest, since lack of this salt has been shown to limit plant life in the upper illuminated layers in the tropics and in temperate regions during the summer months, and upon such plant life—diatoms and peridinians—the rich animal life of the sea depends. Numerous other observations of biological and oceanographic interest are also to be made.

IN *Discovery* for March, Miss Moya Jowett describes the interesting but little known medieval town of Domme and its surrounding country in the valley of the Dordogne. Domme was at one time of considerable importance from the military and economic point of view, as the surrounding area was covered with dense forest, and the only safe method of trade and travel was by water. Near by is the castle of Simon de Montfort, here best known for his massacre of the Albigenses who then held the town. It was the outpost of English territory, and changed hands several times. Many interesting buildings of this period still stand and make the town well worth a visit; but an added attraction is its proximity to Les Eyziès, the centre and capital of the palæolithic cave district of the Dordogne. At the conclusion of her article, Miss Jowett informs her readers that arrangements are being made for a small party interested in archæology to visit Domme and Les Eyziès for a fortnight at Easter at a low cost. The party will stay for one week at Domme and for one week at Les Eyziès, and at the latter place will have the unusual privilege of being conducted over the caves by M. Peyrony. Particulars of the tour may be obtained through the Editor of *Discovery*.

ONE of the earliest uses of electricity was in connexion with lighthouse communication. Carbon arc lamps were employed, and both the lamps and the electric generators used needed constant supervision. A great step forward has recently been made by the use of gas-filled lamps for this purpose. We learn from the *Osram G.E.C. Bulletin* for February that the gas-filled lamps now in use are of very large size, some requiring four kilowatts to keep them in normal operation. The filaments operate at 80 volts, so the lead-in wires have to carry 50 amperes, and have a cross-sectional area of $\frac{1}{10}$ sq. in. The solution of the problem of making a vacuum tight seal between glass and wire of this thickness required a year's research work. In the event of a lamp failing it is necessary that it be immediately replaced. This is done by having a reserve electric lamp, and in addition an emergency acetylene light. Such well-known lighthouses as those at Pendeen, Lizard, Hartland, Burnham, and Skerries have all been fitted with gas-filled lamps. In the case of the Lizard lighthouse, which originally contained an arc lamp working at 30 volts and having for a source of power one or two French alternators between forty and fifty years old, complete conversion of the plant was necessary. As the alternators were still sound, they were utilised and connected to the lamp by a transformer. The whole of the lighting equipment has been made automatic, and an automatic winding device has been added to the clockwork which rotates the lenses. These lamps have proved themselves trustworthy for lighthouse and lightship service and give economic results.

We much regret to announce the death, on Mar. 19, at the age of eighty-five years, of Sir David Ferrier, F.R.S., emeritus professor of neuropathology, King's College, London.

A large earthquake was recorded at Kew Observatory at 5 hr. 20 min. 51 sec. G.M.T. on Mar. 16. The epicentre is estimated to have been about 8400 miles away.

The appointments made by the Secretary of State for the Colonies during the month of February, in addition to those for the East African Agricultural Research Institute, Tanganyika Territory, which were mentioned in Nature of Mar. 17, include the following: Dr. H. Scott, entomologist, Iraq; Mr. J. L. Illingworth, curator and agricultural superintendent, Virgin Islands; Mr. C. B. C. Handley, assistant agricultural officer, Kenya; Mr. H. Marsland, cotton investigator, Agricultural Department, Tanganyika Territory; Mr. R. S. Kyle, veterinary officer, Tanganyika Territory.

At the annual general meeting of the Optical Society, held on Mar. 8, the following officers and new members of council were elected for the session 1928–1929: *President*, Dr. R. S. Clay; *Vice-Presidents*, Mr. D. Baxendall, Mr. H. H. Emsley, Mr. J. Guild, Mr. F. C. Watts; *Hon. Treasurer*, Major E. O. Henrici; *Hon. Secretaries*, Prof. A. F. C. Pollard and Mr. W. B. Coutts; *Hon. Librarian*, Mr. J. H. Sutcliffe; *Editor of Transactions*, Dr. J. S. Anderson; *New Members of Council*, Mr. O. Aves, Mr. T. Chaundy, Dr. C. V. Drysdale, and Mr. A. Whitwell.

The ninth International Congress of Psychology will be held at Yale University in New Haven, Connecticut, U.S.A., probably in August or September 1929. The officers of the Congress are as follows: President, J. McKeen Cattell, of New York; Vice-president, James R. Angell, of Yale University; Secretary, Edwin G. Boring, of Harvard University; Treasurer, R. S. Woodworth, of Columbia University; Foreign Secretary, Herbert S. Langfeld, of Princeton University; Executive Secretary, Walter S. Hunter, of Clark University; chairman of the Programme Committee, Raymond Dodge, of Yale University; chairman of the Committee on Arrangements, R. P. Angier, of Yale University. This is the first meeting of the Congress in America, and it is expected that it will be truly international in character. It is hoped in the United States that the appointment of some foreigners for lecturers and lectureships will be arranged near the time of the Congress, so that foreign attendance will be increased.

We are informed by the Smithsonian Institution of Washington that large editions of two maps of the world, showing the 387 stations from which data were obtained for "World Weather Records" (Smithsonian Miscellaneous Collections, Publication No. 2913), are available. In one of these maps the world is represented as an ellipse, parallels of latitude being parallel straight lines and meridians of longitude arcs, and the other shows the northern and southern hemispheres on a zenithal projection. Each map is on a sheet of about 11 in. × 16 in., and copies can be obtained on application to the Smithsonian Institution at 5 cents a sheet, or 4 dollars a hundred sheets.

The Kodak X-Ray Department will in future be known as the "Medical Department," as it includes in addition to the Radiography Section a Clinical Photography Section and a Medical and Surgical Cinematography Section. For work in the last section the 'Ciné-Kodak' is employed, and it has accessories which take pictures at four times the normal speed without increasing the rate of cranking, or one picture only at each revolution of the crank, thus allowing pictures to be taken at any desired slow rate. In conjunction with a microscope, this slow movement is specially useful in connexion with bacteriological and pathological work. Further details of these and of the Rheinberg colour filters for clinical microscopy, which in conjunction with the substage condenser, give differential colour illumination, are given in the December number of the *X-Ray News and Clinical Photography*, published bi-monthly by Kodak Limited.

The Streatfeild Memorial Lecture for 1927 was delivered last November before the Institute of Chemistry and past students of Finsbury Technical College by Mr. O. F. Bloch, and is just issued in pamphlet form by the Institute. Mr. Bloch took as his subject "The Chemist in the Photographic Industry," and after a personal tribute to Mr. Streatfeild and some general remarks, passed to the problems of light sensitivity and the latent image. He gave twelve facts or questions which must be accounted for or answered by any theory before it can be generally accepted. He then passed in short review the work that has been done in late years and the suggestions that have been made towards the solution of these problems.

Dr. James F. Norris, Director of the Research Laboratory of Organic Chemistry of the Massachusetts Institute of Technology, has undertaken the consulting editorship of the International Chemical

Series, published by the McGraw-Hill Book Company. Dr. Norris succeeds the late Dr. H. P. Talbot, who was also at the Massachusetts Institute of Technology, where he and Dr. Talbot had been associated for considerable periods since 1895. Dr. Norris was president of the American Chemical Society in 1925 and 1926.

Applications are invited for the following appointments, on or before the dates mentioned :—A curator of the Art Gallery of Kingston-upon-Hull—The Town Clerk, Guildhall, Hull (Mar. 30). An assistant in the Department of Scientific and Industrial Research, chiefly to make translations and abstracts of articles dealing with radio-telegraphy—The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (April 4). A woman accountant and lecturer on book-keeping at the Swanley Horticultural College for Women—The Secretary, Horticultural College for Women, Swanley, Kent (April 7). A secretary to the Association of Special Libraries and Information Bureaux—The Chairman of Council, Association of Special Libraries and Information Bureaux, 38 Bloomsbury Square, W.C.1 (April 9). A Principal of the Dudley Technical College—The Clerk to the Governors, Education Offices, Dudley (April 13). A junior scientific officer on the Air Ministry Scientific Research Staff, primarily for duty at the Royal Aircraft Establishment for research in applied physics, chiefly in connexion with aeronautical instruments — The Chief Superintendent, R.A.E., South Farnborough, Hants (April 13—quoting A.265). An adviser in agricultural economics for the Western (Bristol) Province—The Registrar, University, Bristol (April 14). Professors of geography, medieval history, Egyptian and oriental history prior to Græco-Roman times, and of classics and Græco-Roman history respectively, in the Egyptian University, Cairo—The Director, Egyptian Educational Office, 39 Victoria Street, S.W.1 (April 30). A professor of geology in the Egyptian University, Cairo—The Dean of the Faculty of Science, Egyptian University, Cairo (April 30). A second and mathematical master at the City of London School—The Secretary, City of London School, Victoria Embankment, E.C.4. A clinical pathologist at the Crichton Royal Mental Hospital, Dumfries—The Physician-Superintendent, Crichton Royal Mental Hospital, Dumfries.

Our Astronomical Column.

Skjellerup's Comet.—News has been received from the Observatories of the Cape and Johannesburg, that this comet, which was so brilliant in December, has now been photographed in a dark sky on its emergence from the sun's neighbourhood ; its photographic magnitude was 8·9, and Mr. Wood notes that he hopes to be able to follow it for a long time. Since most of the observations in December were somewhat wanting in precision, owing to the absence of comparison stars, these new observations will be of great value for improving the orbit elements. Out of the list of observed positions the following nearly simultaneous observations at the two observatories are selected ; Cape, Feb. 11·11875 U.T., R.A. $18^{\mathrm{h}}\ 58^{\mathrm{m}}\ 32^{\mathrm{s}}{\cdot}77$, S. Decl. 27° 0′ 43·7″ ; Johannesburg, Feb. 11·08398, $18^{\mathrm{h}}\ 58^{\mathrm{m}}\ 31^{\mathrm{s}}{\cdot}01$, S. 27° 0′ 13·3″.

Dr. A. C. D. Crommelin has computed the following orbit :

$$\begin{array}{ll} T & 1927\ \text{Dec.}\ 18{\cdot}1671\ \text{U.T.} \\ \left.\begin{array}{l} \omega\ \ 47\quad 8{\cdot}82 \\ \Omega\ \ 77\quad 14{\cdot}90 \\ i\ \ \ 85\quad 12{\cdot}81 \end{array}\right\} 1927{\cdot}0 & \\ \log q & 9{\cdot}24579 \end{array}$$

The comet remains in high south declination until it is out of sight ; but it should be visible for some months. The observations up to February give no indication of appreciable deviation from a parabola.

Preparations for the Near Approach of Eros in 1931.—In less than three years, this little planet will approach the earth within some 16 million miles, which is not much more than half its distance early in 1901, when it made its nearest approach since its discovery in 1898. An extensive parallax campaign is already planned ; the first essential is to obtain accurate positions of a large number of stars lying near the track of the planet ; this work is being undertaken at many observatories, including Greenwich and Mount Hamilton. A *Daily News Bulletin*, issued by Science Service, Washington, reports that Dr. R. H. Tucker has determined the positions of 821 stars in the first series, and of 402 stars in the second series ; the latter were observed in 77 working nights "during the best observing season at Lick Observatory in 30 years." British observers would give a somewhat less flattering report of last year's weather.

Eros is in opposition next September, in north declination 5° ; but its magnitude will then be only 11, whereas it will rise to 7 in January 1931.

University Observatory, Oxford.—The *Annual Report* of the Visitors of the University Observatory, presented to Congregation on Feb. 28, directs attention to the progress of the catalogue of stars to the eleventh magnitude, for which the co-operation of eighteen observatories was secured at Paris in 1887. The Oxford Observatory was the first to complete its share in manuscript, though circumstances caused some delay to its production in type. After its completion it was found possible to render material assistance to the Vatican Observatory, the publication of the contribution of which is now in sight. The Director has undertaken the chairmanship of the international Committee charged with this work, the completion of which is now showing signs of possible attainment.

The connexion of the seismological work initiated by Milne, undertaken provisionally by Oxford in 1918, has become gradually established with the University Observatory. Fresh accommodation for the seismographs is being provided in the basement of the library, now in course of extension.

Dr. Fotheringham has detected numerical errors in the determined mass of Venus which have a bearing on terms in the sun's longitude. His work on the secular accelerations of the moon has been recently confirmed by the identification of the eclipse of Ur, 2283 B.C.

Weather conditions interfered materially with the joint eclipse expedition to Southport from the Radcliffe and University Observatories. Photographs, however, were taken, and the programme of work was successfully carried through.

Research Items.

Hawaiian Somatology.—The late Louis R. Sullivan, while in Honolulu in 1920–21, made a number of measurements of Hawaiians which it was his intention to study comparatively in relation to other Polynesian material collected under the auspices of the Bernice P. Bishop Museum and the American Museum of Natural History. This material has now been edited and arranged by Dr. Clark Wissler for publication as *Memoir 9, No. 4, of the Bernice P. Bishop Museum*. Dr. Clark Wissler has added comparative notes based upon the Polynesian material from Samoa, Tonga, and the Marquesas. In stature the Hawaiians are the shortest, next in order being the Marquesans and the Maoris. In cephalic, fronto-parietal, zygomatico-frontal, and zygomatico-gonial index, the Hawaiians lead, as they do in head width, minimum frontal, and begonial width. From this it appears that the Hawaiian face and head is relatively wide, whereas in transverse and vertical diameter the head and face are short. The nose is intermediate. Considering all measured characters as of equal weight, the Hawaiians resemble more closely the Tongans and the Marquesans than they do the Samoans. Hawaiians show more straight hair and more brown hair. They exceed in flatness of nose, the order of the transverse axis being Hawaiians, Marquesans, Samoans, Tongans.

Zoology in India.—In his presidential address to the section of Zoology of the fourteenth Indian Science Congress held at Lahore in 1927, recently published by the Asiatic Society of Bengal, Major R. B. Seymour Sewell remarked that in India zoology is still in the stage in which taxonomy must be the first line of research, but he emphasised the paramount importance to the country of the study of ecology and bionomics and hence of more field researches. He pointed out the advantages of team-work in the field by zoologists, botanists, and chemists, so that not only the fauna, but also the associated flora and the chemical composition of the soil and water might be investigated. Failing such collaboration, there is much that a zoologist should be able to do for himself; for example, the estimation of hydrogen ion concentration, the amount of dissolved gases, and the salinity of sea-water, for the operations involved have been simplified and standardised provided the necessary apparatus is available. He also referred to the importance of a study of meteorological conditions in relation to investigations of the fauna of Indian seas, and stated that there is evidence of long period oscillations, of the nature of 'seiches,' which bring up from considerable depths masses of water that have a higher salinity than the normal surface water, and hence exert a profound effect on the fauna. Superimposed on these long period oscillations of salinity is a double diurnal oscillation brought about by an upwelling from a depth of probably 50 to 100 fathoms, and there is evidence that this is accompanied by changes in the plankton. He referred to the vertical migrations of plankton recorded in European waters and expressed his doubts as to whether the small organisms could make their way in the time available from and to the levels to which they are said to migrate, in some instances 200 fathoms. He considers it highly probable that in Indian waters the 'migration' of the plankton is really largely a 'translation.'

Ectodermal Placodes in the Head Region of a Sparrow Embryo.—Mr. Frank Goldby (*Jour. Anat.*, vol. 62, 135-138; 1928) describes a remarkable series of ectodermal placodes which were found in a sparrow embryo. These placodes, six in number, were found on the right side only of the embryo, in series with the auditory placode, two posterior and four anterior to it. The asymmetry of the series, their irregularity in size, and the fact that they correspond to no adult structure, suggest that they are vestigial in character. Their position and their obvious arrangement in series with the auditory placode suggest that they represent traces of the acoustico-lateral system of anamniota. The occurrence of placodes of this kind in an amniote is unique.

Embryology and Musculature of Insects.—The greater part of the December issue of the *Quarterly Journal of Microscopical Science* is devoted to two papers on common insects. In the first of these, L. Eastham records his observations on the embryology of *Pieris rapæ*, rightly believing that an account of the developmental stages so readily obtainable will be helpful to teachers and advanced students. Cleavage begins within the first hour after oviposition, in sixteen hours the blastoderm is complete, at twenty hours the embryonic rudiment is distinguishable, gastrulation begins at twenty hours, and is completed from forty-eight to sixty hours after fertilisation. Of the nuclei resulting from cleavage, those destined to form blastoderm move peripherally to the cortical layer; the remainder are left in the yolk as vitellophags. The movement peripherally of the nuclei is attributed partly to a streaming of the cytoplasm which carries the nuclei. The development and changes in form of the embryonic rudiment are described. Gastrulation is effected by overgrowth of the middle plate by two lateral plates and the endoderm is formed as proliferations in the position of the future mouth and anus. In the second paper, Guy D. Morrison gives a detailed account of the muscles—including their histology and function—of the adult honey-bee. The musculature of all three castes is described, the histology and physiology of the nervous system, and the mechanics of respiratory movements are carefully considered.

Fission in Starfishes.—In notes on New Zealand starfishes (*Records, Canterbury Mus.*, 3, December 1927), E. W. Bennett supports the view that in those species in which the number of rays is more than five, this is due to reproduction by transverse fission. Out of 153 specimens of *Allostichaster insignis*, 132 were six-rayed or potentially so, and he states that fission undoubtedly occurs, this being indicated not only by the size and disposition of the rays, but also by the presence of a groove across the disc. It is equally certain that after fission the new arms are grown almost invariably in threes, which would account for the preponderance of six-rayed individuals. In *A. polyplax*, four new rays are produced after fission, and the characteristic number of arms in this species is eight. Autotomy has long been believed to occur in *Coscinasterias calamaria*, and the author states he has verified this from a specimen in an aquarium.

A Meristic Variation in a Female Nematode.—Mr. G. Henderson Cassidy, Hawaiian Sugar Planters' Experiment Station, Honolulu T. H., writes stating that in material collected by Mr. C. E. Pemberton in Menado, Celebes, and examined in Honolulu in November 1926 by Mr. Cassidy, were several specimens of the genus Dorylaimus, one adult female specimen of which, 1·05 mm. long, presented an unusual variation. It showed two vulvæ identical in formation, presenting no abnormality of structure and both situated on the median line of the ventral surface 0·062 mm. apart. There were two reflexed ovarian tubes, the anterior arising from the anterior vulva and the posterior from the posterior vulva.

Chromosome Mutations in Garden Stocks.—In a combined study of the genetics and cytology of stocks (Matthiola) by Dr. Howard B. Frost and Mrs. Mann Lesley (*Jour. of Heredity*, vol. 18, No. 11), a series of trisomic mutations (with an extra chromosome) have been obtained, similar to those already known in Œnothera and Datura. The stocks have seven pairs of chromosomes. Four of the trisomic forms, called Smooth, Crenate, Narrow, and Dark, are of common occurrence, and apparently each contains a complete extra chromosome. In at least three others (Large, Slender, and Small) the extra chromosome is a fragment only. Among the progeny of Slender plants an occasional Narrow Slender mutant appears. This has, in addition to seven pairs of chromosomes, a large and a small unpaired extra. Resemblances between Small and Smooth suggest that the very small extra chromosome of Small is a fragment of the extra one found in Smooth. These mutants differ in earliness, flower-size, and to some extent in leaf-shape. Their offspring include tetrasomics (14 + 2) in which the peculiarities are more extremely expressed. Slender × Crenate gave one plant, the leaves of which combined the narrowness of Slender and the dentation of Crenate. It is said to have one extra chromosome, short like that of Slender, and another long, as in Crenate. These forms all show much sterility, and in the descendants of Crenate a form also with 15 chromosomes appears, called Crenatoid. This seems to bear the same relation to Crenate that *Œnothera semilata* does to *Œ. lata*.

Precarboniferous Plants from Australia.—Prof. W. H. Lang and Miss Isabel Cookson have just published a report on some very early Palæozoic plants from Victoria, Australia (*Memoirs of Manchester Lit. and Phil. Soc.*, vol. 71, No. 5). These plants have been collected from rocks generally regarded as of Yeringian (Upper Silurian) age. The most definite types of plants so far found are: (1) Large shoots with long linear leaves which cannot be closely compared with any known plant, and are of uncertain systematic position; (2) small-leaved shoots that have been closely compared with Thursophyton and more generally with Arthrostigma and *Psilophyton princeps*; (3) smooth-branched axes of various sizes, sometimes with axillary 'bud-like' structures, which have been closely compared with the various remains classed as Hostimella sp. It is considered that such an assemblage of plant remains, looked at in the absence of any information as to their position and locality, would suggest the Early Devonian flora, and perhaps the Middle rather than the Lower Devonian. The authors suggest that the so far scanty plant evidence should be used sparingly in determining stratigraphical successions, which should be delimited by the fauna when, as in this case, it is well represented. The history of the plants could then be related to this geological succession so determined.

Indirect Excitation of Spectra.—The important observation of Prof. Paschen that Al II lines appear in the negative glow of a discharge from an aluminium cathode in pure helium, has been extended to a number of analogous cases by R. Frerichs (*Annalen der Physik*, vol. 85, p. 364). The ions of some metals the spark spectra of which had already been analysed, were produced by the process of 'sputtering,' and were then further excited by a transfer of energy from metastable atoms of helium, neon, or argon. It was found that the degree of excitation possible depended almost entirely on the energy of the inert gas, fewer spark lines appearing with argon than with either of the others. The principle so established was then applied to the still incompletely known spectrum of ionised copper, and should be capable of very considerable extension. A point of more general interest that is raised by this work is that the law governing the transfer of energy in a collision of the second kind is apparently more like that found to hold for ionisation by electron impact than that governing an inelastic collision at a resonance potential.

The Cosmic Rays.—Full details of their 1926 expedition to Bolivia have been published by Prof. R. A. Millikan and Dr. G. H. Cameron in the February number of the *Physical Review*. An outstanding feature of their report is the remarkable consistency which they have now succeeded in obtaining between measurements made with different electroscopes at various places, which is so good that the new results and the earlier Californian readings can all be represented by a single smoothed absorption curve. The progressive hardening of the rays in their passage through the air, which is shown by this graph, seems now to be definitely established, and corresponds to a spectral range of approximately an octave near 4×10^{-4} A. Their conclusion regarding the suggested influence of the Milky Way is that if it has any effect upon the cosmic radiation, the rays coming from it cannot be 6 per cent. greater or less than those coming from the portion of the heavens at right angles. A terrestrial origin in the shape of thunderstorms is even more unequivocally dismissed after their experiments in a sheltered valley in the High Andes, and in the midst of heavy storms at sea. The value now found for the ionisation at sea-level is 1·4 ions per c.c. per second, and is, so far as the investigations go, independent of the shape, wall-material, and volume of the three electroscopes employed.

Magnetic Theory.—The *Proceedings* of the fourteenth Indian Science Congress held at Lahore in 1927, and recently published by the Royal Asiatic Society of Bengal, contains the presidential address to the Section of Mathematics and Physics on some recent magnetic theories, delivered by Prof. D. M. Bose. It deals in the first instance with the application of electron theory to magnetism, and the disagreement which exists between the magneto-mechanical effect as predicted by the theory and the measured effect. It is possible that this discrepancy may be due to the magnetic field produced by the spin of the electron about its own axis, a field which was postulated by Sir J. J. Thomson in his Silvanus Thompson Lecture to the Röntgen Society in June last. There is still disagreement between observers as to whether the susceptibility of a diamagnetic gas is proportional to the pressure, and the introduction by Weiss of $T - T_0$ in place of the absolute temperature T in the Curie law for paramagnetic substances has not been supported by observations. These show that T_0 may be negative although the theory makes it positive, and that for compounds of the same kind in which one atom is replaced by a more susceptible one, T_0 is decreased while theory predicts an increase. The magneton and the recent theories which predict the magnetons in a compound from its chemical formula are also dealt with.

Automatic Substations in Railway Electrification.—The electrification of the main line railways in Great Britain has brought to the front the problem of the design and maintenance of automatic substations for the supply of electric energy to the trains. Experience has shown that with the usual automatic substations, frequent and lengthy visits by the maintenance staff have not infrequently been a feature of normal operation. The designer's aim, therefore, is to reduce the frequency and duration of these visits, and this necessitates departures from designs which have given every satisfaction in substations which have attendants. This problem is discussed in a paper read to the Institution of Electrical Engineers on Feb. 2 by H. B. Poynder. The chief problem is in connexion with the rotary convertors which have to convert the alternating supply into direct current. As the voltage required is 1500, they are connected two in series. In the early days of the working of an electric traction railway, short circuits on the track have to be regarded as normal operating occurrences. To guard against possible damage to the machines, apparatus for rapidly breaking the circuit has to be installed. To prevent overheating, some 10,000 cubic feet of air per minute has to be passed through each machine. The effect of forced ventilation is to carry with it a large amount of dust, especially in countries where sandstorms occur. As the deposition of dust is very deleterious when the substations are rarely visited, efficient air filters have to be provided. Wet air filters seem to be the best, as there is no fire risk and the air is cooled before it gets to the machine. As substations are usually in out-of-the-way positions, an alarm of fire is rarely given even when black smoke has been issuing for some time. A suggestion is made that a carbon dioxide plant should be installed for the protection of the substation which would operate when small quantities of smoke are present. Photoelectric cells balanced normally would distinguish between the light passed through two long tubes and so automatically release the valve of the carbon dioxide bottle when there was smoke in the substation tube.

NEW ELECTRIC LOCOMOTIVES.—On the electrified main lines of the German State Railways the permissible load on a pair of driving wheels has been increased to 20 tons and the maximum speed has been increased to 68 miles an hour. In order to take advantage of this change it is necessary to have a large motor output per axle. The driving of the axles by individual motors, or better by 'twin motors,' has been found to be the most economical. Two years ago the A.E.G. company supplied the State railways with a new type of electric locomotive having high tractive power and individual axle drive. It has given satisfaction in practice, and 33 locomotives of this type are now being constructed. The aggregate output of the motors on a locomotive on an hourly basis is 3700 horse-power, the weight of the locomotive being only about 110 lb. per rated horse-power. It is claimed in *A.E.G. Progress* for January that it is the lightest single-phase locomotive that has yet been built. Up to a third of full speed, the tractive effort measured at the circumference of the driving wheels is 49,000 lb. It moves easily up an incline of 1 in 8 and round a curve of 600 feet radius The body of the locomotive is divided into three compartments The central compartment contains the main motors and transformers, whilst the two end compartments form driving cabins with control gear. The roof of the machine cabin is divided into five parts so that the various parts of the electrical equipment can be dismantled from above. The ventilating ducts can be closed during heavy snow falls.

BUSCH MICROSCOPES.—A catalogue recently issued by Emil Busch, A. G., Rathenow, gives full particulars of an increased number of types of microscopes now being manufactured by the firm. These include several simple robust models suitable for students' use, as well as more elaborate outfits for biological and petrological routine or research work, and microscopes with body tube of extra large diameter suitable for photomicrography and projection. An interesting feature of the larger models is the fine focussing adjustment, which is effected by means of a spindle supported at both ends. A spiral thread cut on the spindle engages with a wedge-shaped nut. Rotation of the milled head on the spindle produces a lateral motion of the wedge and thereby raises or lowers the body tube through a pillar supported on the wedge by a steel roller. The catalogue also contains lists of objectives and eyepieces, illuminating appliances and various types of mechanical stages. A separate leaflet gives a description of a small portable microscope, the stand, stage, and tube carrier of which are cast in one piece. This instrument may be used for projection purposes, the base of the microscope being threaded and thus capable of being screwed on to the flange of the projection apparatus. Another pamphlet issued by the firm gives directions for the use of microscopes and accessories in the examination of opaque objects by reflected light, and also a description of various types of photomicrographic apparatus. Amongst these is a camera which can be easily attached to the upper end of the body tube of a microscope. The camera is provided with an observation tube which facilitates the focussing of the image and permits of its examination while the exposure is being made. The London agents for these instruments are Messrs. Emil Busch Optical Co., Ltd , 37 Hatton Garden, E.C.1.

INSULATING OILS.—Engineers are using at present a great many oils for insulating purposes. For example, the coils of high tension transformers are as a rule immersed in oil. Hitherto the work of oil refiners has been confined mainly to the production of a good lubricant. Up to the present the problem of producing an oil which will act satisfactorily as an electrical insulator has not been solved, although good progress has been made. Especially is this the case for the oils which are used to impregnate the insulating coverings of paper-insulated cables For cable work it is most essential to keep the dielectric losses as low as possible, while for transformer and switchgear work this is not so important In a paper read to the Institution of Electrical Engineers on Feb. 23 by T. N Riley and T. R. Scott, the requirements for high voltage cables are briefly outlined. Experimental results are then quoted showing the bearing of the physical and electrical characteristics on the finished cable. It is necessary that the paper layers slide smoothly over one another when the cable is handled. It must therefore have the properties of a lubricant. The thermal conductivity of the oil must be high in order that the cable remain cool when working. Although the thermal resistivity of the paper fibre itself is usually less than that of the oil, yet the resistivity of paper contacts between layers of dried paper is of the order of five or six times that of the oil. Imperfect impregnation therefore greatly raises the thermal resistivity. The authors conclude that the elimination of gas 'pockets' in the dielectric is necessary. These spaces not only cause brush discharges and so produce burning and oil oxidation, but they also increase the thermal resistivity. Sensitive methods of measuring the electrical characteristics of the oils are given.

Diseases of the Douglas Fir in Britain.

As is often the case with exotics, there have been one or two scares on the subject of diseases in connexion with the Douglas fir plantations in Britain. A fungus attack reported in a young plantation, when investigated, proved to be caused by an undescribed species of Phomopsis (*P. Pseudotsugæ* Wilson). Then a species of Chermes (*Chermes Cooleyi*) appeared in several parts of the country. A recent leaflet (No. 18) issued by the Forestry Commission, deals with a disease new to Britain, the Douglas fir leaf-cast disease (*Rhabdocline Pseudotsugæ* Syd). The disease is common on the Douglas in the United States, but until within the last few years it had not apparently been noticed on the east of the Atlantic. It has been found on the blue form of the Douglas fir (*Pseudotsuga glauca*) and on the interior dry belt or Fraser River form (*P. Douglasii* var. *cæsia*). Recently it has been also observed on the green Douglas (*P. Douglasii*). This fungus occurs on all forms of the Douglas in the United States, and occasionally becomes epidemic for a season or so. It usually only infests young trees, but attacks larger trees growing on poor quality soils.

Infested needles develop blotches on the under surface during the winter, and at a later date tissues of the leaf on the upper surface, directly above, turn a yellowish brown. By early spring these areas turn a purplish brown, which, contrasted with the green unattacked part of the needle, give the infested foliage a mottled appearance not unlike the resultant mottling produced by *Chermes Cooleyi*. In the latter, however, the presence of the small secretions of white wool on the under surface of the needles serve to distinguish this attack. In the case of the fungus, the mycelium is developed in the leaf and does not pass back into the shoot. About March the hyphæ become numerous on the lower surface of the leaf just beneath the two bands of stomata in the discoloured spots, and it is here that the fructifications are formed. In May the epidermis ruptures, disclosing an orange-coloured layer which bears the spores. Spores are liberated at the time the buds are opening, and infection takes place shortly afterwards on the young needles. Infected needles fall at all seasons of the year. Trees attacked for several years by this fungus may be almost entirely defoliated and may die.

The green Douglas appears to be the least subject to this fungus. So far, the disease has been reported from Peebleshire and from several counties in the south of England. At present it is deemed impossible to suggest any definite remedy, but, in the case of an attack appearing on a few young trees only, the advice is tendered that they should be removed and burnt. In the nursery, spraying with a solution of soap and Bordeaux mixture as practised in the United States is recommended.

In the case of infestations, such as those here mentioned on the Douglas, the real solution would appear to rest on sylvicultural considerations. The planting of pure blocks of rapidly growing exotics is, in many parts of the world, to court disaster in the long run, in one form or another; more especially when the behaviour of the exotic from the sylvicultural point of view, in its new environment, is by no means well understood.

Building Research.[1]

The poet Cowper wrote the well-known couplet, "Knowledge is proud that he has learned so much; Wisdom is humble that he knows no more," and it was Tennyson who said, "Knowledge comes, but Wisdom lingers." These statements are indeed true of building science. The past centuries have witnessed an ever-increasing store of knowledge, wherein precedent, with the natural improvements added for the day current, shows the accretion of knowledge, though not necessarily an accretion of wisdom.

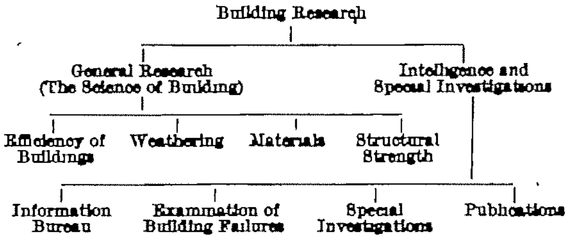
The work of the Middle Ages was largely empirical in nature, though we of to-day would hesitate to deny the wisdom of the ancients of Assyria, Egypt, Greece, and Rome in their palmy days of building activity. Forgetting for the moment the simpler constructive science involved in trabeate architecture, how else than by superior wisdom can we account for the survival of the magnificent relics to the present time—a survival that would have been far less mere relics had it not been for the fortuitous effects of bombardments and the criminal vandalism shown in using some of these buildings as mere quarries?

Though the monks may be credited as having been in the possession of a large amount of useful scientific knowledge in regard to building, as their stately cathedrals show us to this day, yet this knowledge lacked that admixture of wisdom which would have secured to their creations the same defiance of time as appertained to the earlier art. They could calculate to a certain degree the structural basis of the vaulting and groining, so as to promote the attainment of their aim, but the inadequacy of the results is made too painfully evident in these latter days. The poor quality of the stone, the inefficient counterforts and sundry other defects, entail the vast expenditure so frequently witnessed. Even after making allowances for altered conditions consequent upon tunnelling beneath the surface for railways and sewers and the deep excavations for commercial purposes, as well as allowing for the pollution of the atmosphere by reason of industrial processes, yet the charge of inadequate wisdom is justified in its entirety.

A welcome is therefore to be accorded to the present (if somewhat overdue) activity on the part of the Government, whereby scientific research into the capacity and quality of building materials is being undertaken; twofold in its nature, namely, curative research for the purpose of remedying accrued defects, and prophylactic research, which is wisdom in the highest degree, whereby preventive measures may be adopted in time.

The first Report of the Building Research Board, appointed by the Department of Scientific and Industrial Research, has recently been issued; brief as is the period during which the Board has been in existence, there is ample evidence of its utility.

The Board divides its operations into two main sections, (*a*) general research and (*b*) intelligence and special investigations; a reproduction of its 'labour tree' will best conduce to an appreciation of the method pursued:



---

[1] "Report of the Building Research Board for the Period ended 31st December, 1926." (London: H.M. Stationery Office, 1928.) 2*s*.

The subject of weathering has been considered from the various aspects of chemical attack (including solvent action of rain); biological attack, bacteria, lichens, etc.; movements due to temperature and moisture changes; and frost.

It is somewhat on the lines of the bismuth meal, when we note how investigators employ the method of impregnation of stones with coloured resins as a means of tracing the porosity channels of the various stones. Sections of decayed samples upon examination thus enable the formation of sulphates to be studied. In research upon the transmission of chemical solutions as preservatives, it has been demonstrated that the crystallisation induced by evaporation from the face of a wall so impregnated is often a cause of decay; when perished mortar joints have been made sound, evaporation will, in following the line of least resistance, issue from the stone itself, and hence the decay.

Further, it was found that aerobic bacteria rarely penetrate more than an inch below the surface; research into anaerobic bacterial activity has yet to be undertaken. The Board considers, after investigation, that there is no reason to believe that beetles cause decay in stonework; they use the already decayed stone merely as a home, not as a nidus.

Cement and concrete have claimed the Board's attention, and it is shown that the rapid-hardening Portland and high alumina cements are far more impermeable than the ordinary Portland cement. It is shown, too, why the cracking in the cement should be prevented; for if water cannot penetrate the material, then soluble salts cannot be washed out, nor can the steel embedded in reinforced concrete be attacked.

The Board expresses its belief that the deleterious action of frost is not so noticeable in Great Britain as it may be elsewhere. A series of freezing tests upon stone, brick, and tiles indicated general agreement with those of Kreüger in Sweden, where, however, frost is often very disintegrative in its action.

The behaviour of stone preservatives in a town atmosphere is being tested with a series of stone piers, treated and untreated, some with 'dished' tops, others with weathered tops; they are set upon the roof of a Government building in London. Also an illuminating set of experiments has been conducted upon the relation between the wet and dry strengths of bricks and stones.

Most of the Board's work is carried out at its station at Watford, but some investigations are undertaken elsewhere, including the National Physical Laboratory, where an interesting test is being conducted regarding vibration in buildings and fatigue in materials, and also the effect of wind pressure on roofs. The subject of wind pressure upon bridges is also being investigated.

Table 4 is illuminating regarding the diminution of tensile strength which so frequently takes place in neat cement with increasing age; whereas the compressive strengths, shown in Table 5, indicate fairly steady increase. Incidentally, it may be remarked that, later on in the Report, there is some confusion in numbering the tables.

A very valuable branch of research deals with acoustics, hitherto so largely a matter of empiricism in practice. Architects and engineers may now, with some assurance of satisfaction, seek the advice of the Board in this respect; a notable case in point is the series of acoustical experiments undertaken for the Government of India for the new buildings at Delhi.

Limits of space preclude adequate justice being done here to the many or to any of the activities of the Board. We must rest content with a mere brief schedule of such matters as condensation, waterproofing, repairs to old painted ceilings, etc.; the use of wood-cements, wall boards, plaster substitutes, and asphalte; investigation into dry rot, etc. The survey is all too brief regarding an undertaking of which the ramifications are numerous and the labour is indefatigable.

Percy L. Marks.

Plankton Migrations.

Dr. Kenzo Kikuchi, in a paper entitled "Notes on the Diurnal Migration of Plankton in Kizaki Lake" (*Journal of the College of Agriculture, Imperial University of Tokyo*, vol. 9, No. 3, Aug. 1927), recounts some interesting results arrived at by studying certain species in the plankton of Kizaki Lake in the Nagano Prefecture. The pump method was employed, about fifty litres of water being pumped from different depths at periodic intervals and strained through a plankton net. The number of each species was then counted and recorded. These included Cladocera, rotifers, rhizopods, and dinoflagellates, the Cladocera and copepods being specially studied. The lake lies at an altitude of 764 metres, the greatest length being three kilometres, the greatest breadth one kilometre. It is bordered by mountains and plains, and its greatest depth is 29 metres. The temperature ranges in August from 6°·2 near the bottom to 26°·6 at the surface, and in December from 5°·6 to 8°·2 C.

The diurnal migration was found usually to be most distinct in those species living at depths less than 10 metres. Thus *Polyphemus pediculus* and *Bosminopris deitersi* occur at maximum at a depth of 2 metres in the daytime and tend to come nearer the surface at sunrise and sunset, migrating downwards during the day and night. Their maximum near the surface is reached before midnight, after which there is a slight tendency to move downwards. *Daphnia longispina*, living at about 10 to 15 metres during the day, shows no tendency to migrate upwards in the summer, but may move downwards at night. In December, however, when it is spread out from the surface to near the bottom, it shows a slight movement upwards at night, the temperature in the upper layers being lower at that time.

Some interesting observations are made on the various stages from nauplius to adult of the copepod *Diaptomus denticornis*, which migrates upwards at night to attain its maximum at the surface before midnight. In August it was found that the younger the forms the nearer they are to the surface during the day and also the earlier do they reach the surface at night, whilst in the morning they leave the surface later than the older stages. Thus the young stages stay for a longer period near the surface than the older stages. In December there was no diurnal movement in the young forms which had a vertical range from the surface to 10 metres, although the adults still migrated towards the surface at night.

The dinoflagellate *Ceratium hirundinella* was found to range from 2 to 10 metres and to be especially abundant at 5 metres. It moves upwards at night and reaches a maximum at the surface shortly before sunrise.

Most of these migrations show better in August, the number of specimens falling considerably in December.

University and Educational Intelligence.

Cambridge.—Dr. L. Brecher, of Vienna, has been elected to the Yarrow research fellowship in science at Girton College.

Smith's Prizes have been awarded to W. L. Edge, Trinity College, for an essay on "Ruled Surfaces of the Fourth, Fifth and Sixth Orders," and to A. H. Wilson, Emmanuel College, for an essay on "The Two-Centre Problem in Wave Mechanics." Rayleigh Prizes have been awarded to J. A. Gaunt, Trinity College, for an essay on "The Foundations of the Debye-Hückel Ionisation Theory with Application to Gases," and to W. H. M'Crea, Trinity College, for an essay on "The Quantum Theory and the Specific Heats of Gases." The essays of H. P. Mulholland, Queen's College, on "Theorems on Power Series and Dirichlet Series," and of L. Roth, Clare College, on "Discriminant Varieties," are mentioned as being also of distinction.

Dr. Roughton's lectureship in the Department of Physiology has been entitled the lectureship in physico-chemical aspects of physiology.

The Council has reported to the University in favour of accepting for five years from the Committee of the Privy Council for Scientific and Industrial Research an increased offer of £2500 per annum for the maintenance of the magnetic research work now being carried on at the Cavendish Laboratory by Dr. Kapitza, Trinity College. The grant is to be administered by a committee consisting of the Cavendish professor, the University treasurer, Prof. C. T. R. Wilson, and a member appointed by the Committee of the Privy Council.

Further details of the will of the late J. E. Bles, already referred to in these columns, have now been published. The amount of the bequest, which is subject to the life interest of his widow, is likely to be above £30,000, in addition to instruments, books, and fittings and contents of Mr. Bles's private laboratory. The first object of the bequest is the foundation of a Charles Darwin professorship of animal embryology, to be studied and taught from a purely scientific aspect, as distinct from an economic, technical, or medical aspect. If when the money becomes available the University already possesses such a chair, properly endowed, the subject of the new chair shall be bio-physics, the application of physics to a study of living plants and animals. After every twenty-five years a consultative board is to decide on the subsequent application of the trust fund, provided that the income of the fund is devoted to the promotion of a branch of biology as a pure science and that none is devoted to the purposes of economic, technical, or medical biology.

Dublin.—The Senate of the University has approved the conferment, on the recommendation of the Board of Trinity College, of the honorary degree of Sc.D. on Dr. G. L. Streeter, Director of the Carnegie Institution of Washington, Baltimore, Maryland, and Prof. A. S. Eddington, Plumian professor of astronomy and experimental philosophy in the University of Cambridge.

London.—Keddey Fletcher-Warr Studentships, each of the value of £200 a year for three years, have been awarded to Dr. G. F. J. Temple, for research on the application in integral equations to the study of vibrations and stability and to other problems of mechanics and mathematical physics, and to Mr. C. P. Snow, for the study of molecular spectra with special reference to molecular structure.

Oxford.—A proposal has been started for the establishment of a Common Room or Club for the use of men who are members of the research or teaching staff of the Museum departments and similar institutions. The need for such a scheme is especially felt in the case of those workers who do not enjoy the usual privileges of fellows of Colleges. If sufficient support is forthcoming, it is intended to call a meeting of those concerned in order to elect a committee for the consideration of details.

The School of Geography and the Committee for Anthropology have published their respective programmes for the ensuing term. These include lectures and instruction on land forms of western Europe; chronological sequence in the Pleistocene period; methods of physical anthropology; human hybridisation; man and the Pleistocene epoch; primitive language in its relation to thought.

The annual Congress of the National Union of Students, to be held at Oxford at the end of March, will be opened by Sir Michael Sadler, Master of University College, Oxford, with an address on "The Future of the Universities." Other speakers on the main theme of the Congress, "Quo Vadis?" will include Sir Oliver Lodge and Prof. Burstall, of the University of Birmingham. A discussion on "University Problems" will be opened by Prof. Patrick Geddes, of Montpellier. Mr. John Galsworthy has consented to speak on "Man and Beast" at a meeting of the University of London Animal Welfare Society to be held during the Congress.

As a result of a conference recently convened by the London School of Hygiene and Tropical Medicine, which was attended by representatives of the Colonial Office, the India Office, the Ministry of Agriculture, the Department of Overseas Trade, and many important business organisations with interests in the tropics, it has been decided to make arrangements at the School for courses of instruction in hygiene for men and women—especially employees of business firms and official bodies—proceeding to the tropics. Inquiries regarding the courses should be addressed to the Secretary, London School of Hygiene and Tropical Medicine, Malet Street, London, W.C.1.

Shortly after the death, on April 4 last, of Prof. D. A. Gilchrist, a fund was opened to establish a memorial commemorating his work while professor of agriculture at Armstrong College, Newcastle-on-Tyne. A sum of about £480 is now available for this purpose, and it is proposed to found prizes, one at the Newton Rigg Farm School and others at the School of Agriculture at Armstrong College. The latter will be available until the death of Mrs. Gilchrist, when a sum of £3000 comes to the College for two scholarships under Prof. Gilchrist's will; the memorial prizes will then cease, and the money be devoted to support a research exhibition tenable at the College.

The Air Ministry announces that a number of openings are available for young men to be trained as pilots in the Air Force Reserve. Up to sixty candidates will be accepted. Applicants must be of good education and physique, but need not have had any previous flying experience. They must be more than eighteen and less than twenty-five years of age. Selected candidates, after passing an examination by a medical board, are nominated to commissions in the Reserve as pilot officers on probation. When undergoing training an officer receives, generally speaking, the same pay and allowances as an officer of the same rank on the active list. Further details can be obtained from the Secretary (S. 7. c.), Air Ministry, Adastral House, Kingsway, London, W.C.2.

Calendar of Customs and Festivals.

March 25.

Fifth Sunday after Lent, the ancient Passion Sunday, also known as Care Sunday. The word "Care" here refers to a custom of the north of England and Scotland of giving away and eating grey peas which have been fried in butter after being soaked overnight. These are called "carlings." The Sunday on which they were eaten at an entertainment was also called "Carle" Sunday. This custom has no obvious connexion with any explanation of "Care" Sunday suggested by ecclesiastical writers. It is not unreasonable to conclude that the name of an older custom has been adapted to a Church festival. "Carle," it is suggested, is related to "ceorl," a country fellow or labourer, which would make it a rural festival. The "carling groat" is a Yorkshire custom that every labourer should repair to the village alehouse to have a drink of ale free. Anyone who did not comply would succeed in none of his undertakings in the coming year. Another name for the day found in the Isle of Ely, was "Whirlin Sunday," when each family made "Whirlin Cakes." The day is therefore clearly linked up with some form of rejoicing. In some of the observances of "Carrying out the Death," cited by Frazer in "The Golden Bough," peas are specially mentioned as part of the feast which takes place after the procession. Brand, who refers to the dole of soft beans mentioned in the Roman Calendar as given away at funerals, and the use of peas and beans in the Parentalia, the Roman festival connected with the souls of the dead, also quotes Plutarch as saying that pulse was of the highest efficacy for invoking the Manes.

Lady Day. The Annunciation of St. Mary.—A festival which was always carefully observed in England. The Synod of Worcester, A.D. 1240, forbade all servile work on this day. An exception was afterwards made in favour of agriculture. If it fell in Lent it was postponed, as was customary; but the church of Notre Dame de Puy had the privilege of making it override Good Friday when it occurred on that day, and great indulgences took place in the church.

It is not surprising that a date of such importance in Christian belief should have appealed to the minds of the early Christians as a time which by its very sanctity would be the necessary occasion of other events of importance in sacred history. It was also the date of the Crucifixion; and in a set of ancient verses it is noted as a day on which many miraculous events took place: Adam was created; Abel, the first martyr and the first man to die, was killed; Melchisedek made his offering; Isaac was offered up; John the Baptist was beheaded; the penitent thief was accepted by Christ, and so forth. Martyrologies add the crossing of the Red Sea and the wiping of the face of Christ by St. Veronica. It will be remembered that the features of the Christ were imprinted on the cloth with which this was done.

The idea which underlies the Annunciation is one which has been familiar to students of primitive thought since the researches of Spencer and Gillen among the Arunta of Central Australia. It is now known that these tribes are not alone among primitive peoples in failing to appreciate the physiological facts of paternity. Among the Arunta it is believed that conception takes place solely by the entry of a spirit into the body of the future mother. It is from this idea that beliefs in reincarnation arise, as can be shown by a comparison of the various forms which they take. Among certain South African tribes, for example, even though they have advanced beyond the more primitive ideas of the Arunta so far as the physiological facts go, it is nevertheless believed that the spirit of an ancestor enters the body of the mother to animate her child, and usually it is known with certainty which of them is thus reincarnated.

St. Simon, boy martyr, A.D. 1475: St. William, boy martyr, A.D. 1144—two of a number of child murders for which the Jews were held responsible.

St. Simon, aged 29 months, was killed on Tuesday in Holy Week at Trent: St. William at Norwich, at the age of 7 years. The point of the accusation against the Jews was that the abduction always took place in Holy Week, the alleged intention being to crucify the child in simulation of the crucifixion of Christ. The first mention of the crucifixion of a boy by the Jews is in the Church History written by Socrates, who states that it took place about A.D. 414 at a place called Immestar in Syria. In England there were a number of cases—one of a child in 1160; a boy, Robert, at Bury St. Edmunds in 1181; and Hugh of Lincoln, whose fate is celebrated in a popular ballad, in 1255. In 1240 a Christian boy at Norwich was circumcised, and was about to be crucified when rescued. Further cases in Germany, France, Bohemia, and Russia are numerous down to modern times, though not all were boys, girls sometimes being murdered. An alleged case in Russia, just before the War, attracted widespread attention.

In addition to the charge of murder by crucifixion, it was sometimes alleged that the motive was to obtain blood for ritual uses at the Passover. In the case of St. Simon, a bowl of blood was discovered in a cupboard in the Synagogue, and it is usually alleged that the death of the victim is effected in accordance with Jewish ritual. It may be noted that the same accusation was brought against the Christians in the early days of the Church by Roman writers. There is no doubt that the medieval populace was influenced against the Jews by primitive superstition about the efficacy of blood and its use in ritual.

March 26.

St. Ludger, Bishop of Munster, A.D. 1809.—A native of Friesland whose legend embodies a record of pagan birth customs. When Liafburg, his mother, was born, her grandmother on the father's side, still a pagan, was enraged that her daughter-in-law had borne no sons. She sent officers to take the babe from its mother's arms before she had had an opportunity to feed it, for it was the custom to kill a child before it had tasted earthly food. It was snatched from the arms of the officer by a servant, who hurriedly placed some honey in the child's mouth, which it swallowed. It could not then be killed.

March 30.

St. Regulus, Bishop of Arles and Senlis, 4th Century.—An incident in his life illustrates the supersession of pagan by Christian shrines. When passing through Louvres, near Paris, he overthrew an idol of Mercury, and built a chapel dedicated to the Virgin.

St. John Climacus, A.D. 606.—An early reference to the Wandering Jew is contained in the record that when St. John was entertaining 600 pilgrims on Sinai, a stranger habited in linen, after the ancient Jewish fashion, appeared among the attendants and vanished after the feast was over. St. John concluded it must have been Moses, who had revisited Sinai for a brief moment. Numerous Hebrew legends of a similar character call the mysterious stranger Elijah. Among the Arabs a similar undying man is known as El Khoudir, friend and instructor of Moses.

Societies and Academies.

LONDON.

Royal Society, Mar. 15.—**J. D. Cockcroft**: The design of coils for the production of strong magnetic fields. One of the most difficult problems in the production of magnetic fields of the order of half a million gauss is to construct a satisfactory coil. Even in the method developed by Kapitza, in which the field is only produced for a fraction of a second, the heating of the coil is a serious limitation, whilst the electromagnetic forces on the coil give rise to stresses in the copper of the order of 7000 kgm./sq. cm. beyond the elastic limit of ordinary copper. This paper develops methods for selecting dimensions of the coil which will produce the greatest field for given power input, and for fixed allowable temperature rise.

D. Jack: The band spectrum of water vapour. The band λ3428 has been analysed from new measurements. For this band the emitter has the same initial state as for band 3064, and same final state as for bands 3122 and 2875. Consequently, band 3428 corresponds to transition $0 \rightarrow 1$ of vibrational quantum number. The initial and final values of the moments of inertia for the vibrationless state are, $I_0' = 1 \cdot 633$, and $I_0'' = 1 \cdot 498$, in units 10^{-40} gm. cm.^{2}. Corresponding nuclear separations of an OH ion are, $r_0' = 1 \cdot 022 \times 10^{-8}$ cm., and $r_0'' = 0 \cdot 979 \times 10^{-8}$ cm.

R. d'E. Atkinson: Statistical experiments on the motion of electrons in gases. Various papers of Prof. Townsend and his assistants claiming results which are not reconcilable with the quantum theory are discussed. In particular, the presence of metastable states in the term-systems of the gases undermines, at two different points, a theory which has implicitly assumed their non-existence. The experimental methods employed are statistical, and introduce many unknown quantities, but within wide limits of obtainable accuracy no disagreement is found with the quantum theory.

Lord Rayleigh: The light of the night sky: its intensity variations when analysed by colour filter (3). The intensity of the light of the sky at night has been observed by collaborating workers at a number of stations scattered over the world. Colour filters were used to separate as nearly as may be the region of the green auroral from the red and blue regions of the spectrum on either side. The broad result is that the intensity in each component has the same general values and range of intensities (four or fivefold) previously found for England. Much of the variation is irregular, and has not been found to be correlated at the different stations. Five years' observation in England indicates a definite annual periodicity, which survives the process of averaging the same month (for example, February) for each year; amplitude of variation corresponds to intensity ratio of 1·6; maximum is in October. The scanty available evidence suggests a similar variation in the southern hemisphere, with opposite phase, maximum in April.

W. Wilson: Relativity and wave mechanics. The equations of motion of a charged particle can be derived from those of an uncharged (which represent a geodesic in space-time continuum) by substituting for the mechanical momentum an extended momentum. This suggests that we regard the world-line of the charged particle as a geodesic in 5-dimensional continuum. With this modified relativity theory as basis, a generalised form of Schrödinger's equation for a single particle is deduced.

A. E. H. Love: The bending of a centrally loaded plate supported at two opposite edges. The question is of some importance in connexion with the experimental determination of elastic constants, inasmuch as it has been proposed to determine such constants, especially of crystals, by measuring, by an interferential method, the central deflection of a rectangular plate, supported at two opposite edges, and bent by concentrated pressure applied at the centre of one of its faces. The object of the paper is to obtain such a formula in the case where the material is isotropic. The problem, a purely mathematical one, is solved completely, and calculated numerical values of central deflection are tabulated for various values of the ratio breadth to length, and for two values of Poisson's ratio for the material.

M. Nottage: Studies in adhesion (3). The adhesion–molecular composition curves of three sets of binary mixtures have been determined and compared with the corresponding melting-point–molecular composition curves. Transition points occur at corresponding points on the two sets of curves and are generally points of definite molecular composition.

Optical Society, Feb. 16.—**W. M. Hampton**: An investigation into the beam from a standard lighthouse lens. The distribution of light from a third order Fresnel panel was measured, using two different light sources, a standard petroleum vapour burner and a 3 kw. lighthouse cruciform lamp. A complete theoretical discussion of the factors affecting beam candle-powers is worked out and tables are provided for the calculation of the beam candle-power from any apparatus using any light source.—**R. Kingslake**: The 'absolute' Hartmann test. According to the ordinary methods of performing the Hartmann test, the assumption is made that all the rays cross the optical axis. As a matter of fact, this is very far from the truth, especially in the case of the large astronomical objectives and mirrors to which the Hartmann test is most generally applied. In the present paper a brief description is given of a modified test in which each 'ray' is treated on its own merits, and its absolute deviation from the ideal path is determined in both magnitude and direction. This method incidentally leads at once to the well-known criterion *T* of Hartmann, which is now generally adopted in the comparison of large telescopes.—**R. S. Clay and Sir Richard Paget**: A portable stereoscopic kaleidoscope. No new optical principles are made use of in this instrument. It differs from the ordinary kaleidoscope mainly in the fact that the mirrors are of sufficient size to enable objects to be viewed by both eyes and thus to see them in stereoscopic relief. The mirrors are front silvered and are mounted at an angle of 30°, one mirror being vertical. The objects, consisting of coloured silks, artificial flowers, etc., are arranged on a black velvet background on a drum, which is rotated at the open end of the mirrors, and lighted from one side by an incandescent lamp. The stereoscopic relief greatly adds to the charm of the resulting pictures.

Geological Society, Feb. 22.—**C. A. Matley**: The pre-Cambrian complex and associated rocks of south-western Lleyn (Carnarvonshire). With a chapter on the petrology of the complex, by **E. Greenly**. The pre-Cambrian complex of Lleyn occupies the coastal strip from Nevin to Aberdaron and Bardsey Island, and is a detached 'region' (the Mainland region) of the Mona Complex of Anglesey. It is bounded on the east by a great thrust which has driven it over Ordovician strata and the Sarn granite. Its members are now correlated with those of Anglesey. The gneisses, several members of the bedded succession, the plutonic instrusions, and the 'Penmynydd zone of metamorphism' are all represented. The Holyhead group is absent. The gneisses are always found near the boundary-thrust. Both their basic and their acid members are almost identical with those of Anglesey. Their crystallisation and foliation are older than the deposition of the bedded succession. Most of the region is occupied by the Gwna Group. Resting on the Gwna beds are some 300 feet of quartz-albite dust-rocks (Gwyddel beds). They may be a special facies of the Skerries group of Anglesey, with a representative of the Tyfry beds at their base. The gabbros are akin to those of Anglesey, and are regarded as plutonic intrusions belonging to the complex. The tectonics and foliation of the complex resemble in almost every detail those of the complex in Anglesey. Many basic dykes are exposed in the complex, of which the great majority are Palæozoic (post-Llandovery and probably post-Silurian), but earlier than the great thrusting movements after the close of Silurian time. Three Tertiary dykes have been found. The boundary-thrust is certainly a great rupture, which shows no sign of dying out at either end of the exposed part of the complex. The extent of its overdrive cannot be determined, but it should probably be measured in terms of miles, and may have been sufficient to sever the whole plexus of Palæozoic dykes in the complex from their roots.

Physical Society, Feb. 24.—**W. H. J. Childs**: Some methods of estimating the intensities of spectral lines. A critical account is given of methods of spectral photometry applied to the special case of the band spectrum of helium. With the method finally adopted, the line spectrum is photographed in the usual way, and the density of the line photographs is measured. For this purpose the plate is calibrated by illuminating the slit of the spectroscope in a special manner by a tungsten filament lamp, so that upon development the plate exhibits a number of images of continuous spectra of progressively increasing density. From these images may be ascertained (*a*) the relation between intensity of light and density of image, and (*b*) the relation between plate sensitivity and wavelength of the incident light. Density measurements are obtained by a simply constructed selenium cell microphotometer, with which the density contour of each line can be investigated.—**P. W. Burbidge** and **N. S. Alexander**: Electrical methods of hygrometry. Two methods are considered, depending on (1) the change in resistance of organic materials (cotton-wool and human hair) on exposure to water vapour; (2) the change in mobility of ions due to water vapour. In the first case the logarithm of resistance is proportional to the humidity, while in the second the effect produced is too small to permit accurate measurement. Neither method is suitable for general use.

Linnean Society, Mar. 1.—**A. M. Smith**: The Algæ of a bog: five years' observations. Observations were taken at approximately monthly intervals of the algæ of a small Sphagnum bog near Bradford between March 1923 and August 1927. Observations of the temperature and of the hydrogen ion concentration of the water were also made. Two main algæ associations were clearly distinguished: (1) the association of the Sphagnum pools and (2) the association of the mud pools and deeper ditches. After the drainage of the bog in 1923 the Sphagnum association decreased, and the long, slow choking of the bog channels which followed later was accompanied by the gradual extension of this characteristic association. The total quantity of alga in the bog varied with the quantity of water in the bog, and showed little evidence of any check due to low temperatures. The quantity of certain species, however, *e.g.* a sterile species of Mougeotia, showed signs of diminution due to low winter temperatures.—**C. Crossland**: Coral-reefs of Tahiti, Moorea, and Rarotonga. The reefs of Tahiti, in spite of their covering of coral and Lithothamnion, are not extending seaward. The sunk reefs are the eroded remnants of a surface barrier. The lagoons have been excavated in an originally continuous reef, and subsidence is not necessary for the formation of barrier reefs. The adjacent island of Moorea has tilted and drowned its southern coast, with no effect on the form of the reefs. Lagoons and passes probably had their first origins in earth-movements, radial and circumferential cracks opening in the reefs. In Moorea the reduced amount of alluvium brought down allows a more vigorous growth of coral in the lagoons, and the maritime flat is largely composed of coral and is not being washed away. Flats of elevated coral occur in Moorea, which afford another proof that there has been no recent seaward extension of the reef. Rarotonga is usually described as having a fringing reef only, but comparison with Moorea suggests that it once had a lagoon which is now filled in.—**E. Handschin**: Collembola from Mexico.—**W. O. Howarth**: The genus Festuca in New Zealand.

Institute of Metals (Annual General Meeting),[1] Mar. 8.—**G. L. Bailly**: The influence of dissolved gases on the soundness of 70 : 30 brass ingots. Treating the molten metal with nitrogen gave an ingot practically free from unsoundness due to gas. Comparative tests were made on samples of 70 : 30 brass treated with nitrogen, hydrogen, and sulphur dioxide, poured in a series of moulds giving different speeds of solidification, and again no evidence was obtained of unsoundness caused by gas evolution during solidification. It is concluded that if appreciable amounts of gases are soluble in liquid brass, the solubility in the solid state is sufficiently high to retain the gas in solution. The probability is, however, that the high vapour pressure of zinc in molten brass precludes the solution of gas by the alloy.—**A. L. Norbury**: The effect of quenching and tempering on the mechanical properties of standard silver. Standard silver (92·5 per cent. silver, 7·5 per cent. copper) as ordinarily annealed contains a considerable amount of copper (in which some silver is dissolved), distributed in the form of small particles throughout the silver solid solution matrix. By suitable heating (*e.g.* about half an hour at 770° C.) and quenching, these copper particles may be dissolved and retained in supersaturated solid solution in the silver. The alloy in the quenched condition is about 30 per cent. softer and 20 to 30 per cent. more ductile than it is in the ordinarily annealed condition. On suitable tempering the quenched alloy (*e.g.* about half an hour at 300° C.) its Brinell hardness increases by about 300 per cent., and its tensile strength by about 50 per cent., and its ductility falls by about 50 per cent., due to the decomposition of the supersaturated solid solution of copper in silver. The hardening on tempering is accompanied by a decrease in volume and is uniform. The alloy is more resistant to oxidation and tarnishing when in the quenched and tempered conditions than it is when in the annealed condition.—**J. Newton Friend** and **W. E. Thorneycroft**: An example of Roman copper 'soldering' and welding from Uriconium. A Roman iron ferrule from Uriconium appears to have been made by welding two small pieces of iron into a strip, bending it over, and joining the two ends with copper. This appears to be the first example of copper 'soldering' of Roman origin to be examined.—**J. Newton Friend**: The relative corrodibilities of ferrous and non-ferrous metals and alloys. Part I. The results of four years' exposure in the Bristol Channel. The metals examined included tin, lead, nickel, zinc, aluminium, and various coppers and brasses. Nickel, tin, and lead resisted corrosion remarkably well. Of the brasses, screw metal (1·37 per cent. lead) made the best showing. This was closely followed by the nickel-copper (1·75 per cent. nickel). A galvanised iron bar lost less in weight than either the iron or the zinc separately. The aluminium bar was very deeply pitted.—**T. E. Allibone** and **C. Sykes**: The alloys of zirconium. The structures of partial series of the alloy systems copper-zirconium to 35 per cent. zirconium, nickel-zirconium to 55 per cent. zirconium, and iron-zirconium to 30 per cent. zirconium, are given. In each case the system is eutectiferous, and inter-metallic compounds are formed. In the copper-zirconium system the compound Cu_3Zr is found; in the nickel-zirconium system two compounds, probably Ni_3Zr and Ni_4Zr are found in the range of alloys investigated. The solid solubility of zirconium in the pure metals copper, nickel, and iron is in each case very small (less than 0·5 per cent.)—**Tsutomu Matsuda**: On the quenching and tempering of brass, bronze, and aluminium-bronze. These copper alloys containing a proper amount of the second metals may be hardened by suitable heat-treatment. The nature of the temper-hardening was investigated by means of microscopic and dilatometric tests and electrical resistance measurements, and it was concluded that the hardening is accompanied by the separation of α from β or γ, or the decomposition of β or γ into eutectoid, or both of these changes, and probably due to the straining of the space lattice produced by these structural changes.

---

[1] Continued from p. 442.

DUBLIN.

Royal Irish Academy, Feb. 13.—**R. Ll. Praeger**: On some doubtful species of the African section of the Sempervivum group.—**R. Southern**: Salmon of the river Shannon, 1924, 1925, and 1926. This report deals with results obtained from the examination of scales from rod-caught salmon taken at Killaloe, on the river Shannon, during 1924, 1925, and 1926. The proportion of one-year-old smolts is 40·4 per cent., of two-year-old smolts 58·8 per cent., and of three-year-old smolts 0·8 per cent. The average length of the one-year-old smolts is 9·7 cm., of the two-year-old smolts 14·5 cm. The most important group in the 1924 catch was that of the large spring fish, constituting 52·4 per cent. of the catch in numbers; whilst in the 1925 and 1926 catches the small spring fish predominated to the extent of 46·2 per cent. and 51·5 per cent. respectively. The proportion of fish which had previously spawned was 5·5 per cent., 11 per cent., and 4·1 per cent. in the three seasons. Spring fish comprise 80-90 per cent. of the total catch; large spring fish average 26 lb., small spring fish 13 lb. The high average weight of the Shannon salmon is due to the high coefficient of condition (ratio of weight to length) and to the high proportion of the old fish in the catch.—**Miss A. L. Massy**: The Cephalopoda of the Irish coast. Descriptions and particulars were given of the occurrence of all the species of Cephalopoda which have been found in Irish waters. They comprise 31 species and a larval form (Rynchoteuthion).

EDINBURGH.

Royal Society, Feb. 6.—**W. H. Lang**: The flora of the Old Red Sandstone of Scotland: a general survey. The paper dealt with the following types of plant-remains that can be authenticated by specimens. It is evident that the main horizons of the Old Red Sandstone of Scotland have distinct assemblages of fossil plants. Upper Old Red Sandstone—*Archæopteris hibernica* (Berwickshire), ribbed stems (corduroy plant), woody incrustations, and specimens suggestive of Cyclostigma and Archæopteris (Shetland). Middle Old Red Sandstone—*Psygmophyllum Brownii*, Rhacophyllum-like fossil, ribbed stems, black woody stems, *Palæopitys milleri*, *Caulopteris Peachii*, Hostimella sp. (*Psilophyton robustius*, Kidston non Dawson), *Milleria* (*Psilophyton*) *Thomsoni*, *Milleria pinnata*, *Hostimella globosa*, *Hostimella racemosa*, *Pseudosporochnus Krejčii*, *Protolepidodendron Karlsteinii*, *Thursophyton Milleri*, *Hicklingia edwardi*, fructification (Hugh Miller's 'fern'), spore-types. Also from the Rhynie Outlier—*Rhynia Gwynne-Vaughani*, *R. major*, *Hornea Lignieri*, *Asteroxylon Mackiei*, Pachytheca, Nematophyton, casts of large trunks. Lower Old Red Sandstone—*Arthrostigma gracile*, *Psilophyton princeps*, Pachytheca (Strathmore Sandstones); Nematophyton, Pachytheca, *Parka decipiens*, *Zosterophyllum myretonianum* (Carmyllie Beds).—**Sir Thomas Muir**: The theory of Jacobians from 1885 to 1919.—**D. M. Y. Sommerville**: An analysis of preferential voting.

Royal Physical Society, Feb. 27.—**J. S. S. Blyth**: Some observations on the relation of gonadic structure to comb growth in the fowl. Changes in the histological appearance of the gonad coincident with the springing of the comb in the juvenile male of the domestic fowl are described. The increased comb growth and vascularity occurred at a time when the luteal tissue had begun to degenerate rapidly and the production of intra-tubular cells in the prophase of the first meiotic division was approaching its maximum. The latter appears to be the most probable source of the stimulus, but it cannot yet be decided whether the influence exerted on the comb by the gonad is inherent in the cells at this particular stage of maturation or whether it arises from the general increase in cell activity at this time.—**I. J. F. Williamson**: Furunculosis in the Salmonidæ. In recent years the salmon and trout in some British rivers have been attacked by an epizootic disease, known as Furunculosis; this disease has occurred on the Continent since the end of last century, and has also been recorded in America. The cause of the disease is a micro-organism, *Bacillus salmonicida*, which produces a general infection and is found in the blood of diseased fish. The bacillus does not produce disease in warm-blooded animals, but the flesh of affected fish is discoloured and softened and unfit for consumption.

SHEFFIELD.

Society of Glass Technology, Feb. 18.—**D. Starkie** and **W. E. S. Turner**: Note on the ultra-violet ray transmission of colourless bottle glass. Each of eight commercial soda-lime-silica glasses showed a maximum transmission in the green or yellow regions, the percentage of light transmitted then falling off gradually in the violet and near ultra-violet regions until a wave-length of about 3300 A. was reached, when the percentage of light fell off very rapidly to the limit of transmission. The glass containing 0·05 per cent. Fe_2O_3 transmitted down as far as wave-length 2960 A. Four others, each containing 0·07 per cent. Fe_2O_3, transmitted down to 2995 A., whilst the pale green glass with 0·18 per cent. Fe_2O_3 had its limit at wave-length 3175 A. All the glasses, with the exception of the green one, transmitted farther down into the ultra-violet than the average window glass, the limit for which is at about wave-length 3100 A. As further illustrating the relation between transmission in the ultra-violet and iron oxide content, some pure glasses, of approximate composition 75 per cent. SiO_2, 10 per cent. CaO, 15 per cent. Na_2O, containing small accounts of iron oxide, were tested. The iron oxide content and the limit of transmission were: 0·005 per cent. Fe_2O_3, transmission to 2600 A.; 0·008 per cent. Fe_2O_3, transmission to 2660 A.; 0·015 per cent. Fe_2O_3, transmission to 2740 A.—**W. Singleton** and **R. C. Chirnside**: The analysis of opal glasses. The constituents commonly occurring in commercial fluoride glasses were dealt with briefly, but more detailed consideration was given to the determination of boron, zirconium, tin, zinc, and arsenic. Zirconium was determined as pyrophosphate, according to the method described by W. F. Hillebrand. Arsenic was determined after decomposition of the glass by means of hydrofluoric acid. The solution of the glass was neutralised by ammonia, made acid with hydrochloric acid, then the arsenic was precipitated as sulphide. This was filtered, dissolved in caustic potash solution, and the arsenic finally determined volumetrically by titration against standard iodine solution. Fluorine was determined as calcium fluoride in the usual way.

PARIS.

Academy of Sciences, Feb. 13.—**Laubeuf**: Safety apparatus in submarines. Detailed discussion and criticism of various forms of life-saving apparatus applicable to a submarine in cases of accident.—**d'Arsonval**, **Bordas**, and **Besson**: The climatological observatory of Mont-Revard. This observatory has been installed on one of the highest points of the Mont-Revard plateau (1522 metres), and is provided with maximum and minimum thermometers, temperature and humidity recorders, heliograph, rain gauge, anemometer and actinometer, readings being taken three times daily. The results of two years' observations are summarised.—**S. A. Janczewski**: Theorems of oscillation of regular homogeneous differential systems of the fourth order.—**J. Delsarte**: Functional linear transformations and non-Euclidean functional rotations.—**P. Fatou**: Certain systems of differential equations depending on a parameter.—**Maurice Janet**: A system of partial differential equations.—**L. Tumarkin**: The dimensional structure of closed ensembles.—**N. Bogoliouboff** and **N. Kryloff**: The method of finite differences for the approximate solution of the fundamental problems of mathematical physics.—**Frilley**: The spectrography of the γ-rays by crystalline diffraction.—**Francis Perrin** and **R. Delorme**: The measurement of the times of fluorescence of uranyl salts, solid and in solution. The luminescence of uranyl salts has all the characters of a simple fluorescence of long duration. The times measured are of the order of $1{\cdot}0 \times 10^{-4}$ to $6{\cdot}1 \times 10^{-4}$ sec.—**A. Piccard** and **E. Stahel**: The non-existence of the ether wind. A reply to some criticisms of Brylinski.—**P. Chevenard**: The electrical properties of ferro-nickels containing chromium. The allotropic transformation of iron-nickel alloys, rich in iron, is accompanied by an increase in the specific resistance on warming. The addition of chromium lowers the temperature of the allotropic transformation and the thermal hysteresis increases.—**Lucien Cavel**: Contribution to the study of activated sludge. Activated sludges lose their activity with increasing percentage of nitrogen: long aeration removes organic nitrogen and restores the activity. Activated sludges have not the same flexibility in use as bacterial beds, and are liable to be put out of action by changes in the composition of the sewage under purification.—**P. Carré**: The iodometric estimation of phosphoric acid, and the use of sodium bicarbonate in iodometry. In the presence of an excess of alkaline bicarbonate, the results are not exact, owing to the formation of iodate by the action of iodine on the bicarbonate.—**Paul Baud**: A method of manufacturing barium hydrate, starting with the carbonate. Barium carbonate and ferric oxide react at 1150°–1180° C., giving a product containing 56-58 per cent. BaO.—**R. Cornubert**: Orientation phenomena in α-methylcyclohexanone.—**D. Ivanoff**: The preparation of benzophenone by organo-magnesium compounds. The mechanism of the reaction between organo-magnesium compounds and their carbonated derivatives.—**C.** and **M. Schlumberger**: The discovery, near Hettenschlag, of a second salt dome in the plain of Alsace. This salt dome has been detected and its outline determined by an electrical method, based on measuring the mean electrical resistance of the soil on a thickness of the order of 100 metres.—**Daniel Chalonge**: Study of the ozone layer of the upper atmosphere during the night. The results, based on spectrometric data, show that the ozone layer is appreciably stronger during the night than during the day.—**H. Bellocq** and **Ch. Jacquet**: Magnetic measurements in the Basses-Pyrénées, Landes, and Gironde.—**Henri Labrouste**: Magnetic measurements in the north of France.—**Mlle. Eliane Basse**: Some Cretaceous fossil invertebrates from the southwest of Madagascar.—**Robert Lemesle**: Abnormal suberous formations in a Labiate (Hymenocrater).—**Mlle. M. L. Verrier**: The presence and structure of a retinal fovea in *Serranus cabrilla*.—**J. J. Thomasset**: Remarks on the canaliculæ of dental enamel.—**Charles Pérez**: The apparatus for attaching the abdomen to the thorax in decapods.—**F. Maignon** and **E. Knithakis**: The influence of watery diet on the urinary excretion of ketonic bodies in the dog.—**Léon Blum**, **P. Grabar**, and **Joseph Weill**: The influence of mineralisation on the osmotic pressure of the blood proteins.—**L. Ambard** and **F. Schmid**: Diuresis and osmotic pressure of the albumins.—**Louis Lewin**: An intoxicating substance, banisterine, extracted from *Banisteria Caapi*. The active principle has been obtained in crystals, of the composition $C_{13}H_{12}ON_2$. According to Merck, it is identical with harmine, extracted from *Peganum Harmola*, but its physiological effects are not identical with those of harmine. Banisterine may prove to have useful therapeutic applications.—**Ph. Joyet-Lavergne**: The oxido-reducing power of the chondriome.—**Lemoigne**: The formation of an orthodiphenol at the expense of glucides by certain soil bacteria.

GENEVA.

Society of Physics and Natural History, Feb. 2.—**W. H. Schopfer**: Researches on biochemical sexual dimorphism. The author has made a study of carotine from *Mucor hiemalis*, which contains a material with crystalline structure. Its culture in a known nutritive medium (maltose and asparagine) shows that the most marked dimorphism takes place when the ratio of total carbon to organic nitrogen is a maximum.—**Sw.** and **Th. Posternak**: (1) Contribution to the study of the configuration of inositol. (2) A natural optically active inositotetraphosphoric ester. It results from this study that besides the hexaphosphate of inosite existing in all the seeds studied, the wheat embryo contains in preponderating quantity a lævorotatory tetraphosphate.—**L. Duparc** and **E. Molly**: (1) The presence of kenyite on the Abyssinian plateau. (2) Tokeite, a new Abyssinian rock. The authors have collected between Nekami and Addis-Abeka a rock very nearly identical with kenyite from Kenya, discovered by Gregory. They have given the name of tokeite to a rock of the basalt family, with 43·6 per cent. of silica: its texture is porphytic holocrystalline.—**Eug. Pittard**: A mummified head (*tsantsa*) of the Jibaros Indians. It represents one of the smallest described; its horizontal circumference is 200 mm.

Publications of the United States Naval Observatory. Second Series, Vol. 11: Results of Observations with the Six-inch Transit Circle, 1909-1918, reduced under the direction of J. C. Hammond, discussed by J. C. Hammond and C. B. Watts: Catalogue of 215 Stars for 1910.0 from Observations in the Years 1909-1910; Catalogue of 2409 Stars for 1910.0 from Observations in the Years 1911-1918. Pp. iii+712+5 plates. (Washington, D.C.: Government Printing Office.)

Ministry of Agriculture, Egypt: Technical and Scientific Service. Bulletin No. 75: The Perennial Cultivation of Cotton, with special reference to the Cultivation of Ratoons in Egypt. By Dr. James Templeton. Pp. ii+81+11 plates. (Cairo: Government Publications Office.) 5 P.T.

United States Department of Agriculture. Technical Bulletin No. 48: The Western Cedar Pole Borer or Powder Worm. By H. E. Burke. Pp. 16. (Washington, D.C.: Government Printing Office.) 5 cents.

Diary of Societies.

FRIDAY, MARCH 23.

ASSOCIATION OF ECONOMIC BIOLOGISTS (in Botany Department, Imperial College of Science), at 2.30.—R. S. Pearson: Forest Products Research: Research in Progress at the Laboratory at Princes Risborough.—J. F. Martley: The Work of the Oxford Branch.

PHYSICAL SOCIETY (Annual General Meeting) (at Imperial College of Science), at 5.—Ordinary Meeting.—W. D. Flower: The Terminal Velocity of Drops.—Satyandra Ray: On the Longitudinal Waves along a Rod.—J. J. Manley: On the Damping of Mercury Ripples.—Demonstration of *Die Rastermethode* (the Testing of Spherical Aberration by Means of Shadows in an Astigmatic Beam), by J. E. Calthrop.

SATURDAY, MARCH 24.

ROYAL SANITARY INSTITUTE (at Municipal Buildings, Taunton), at 10.30 A.M.—Discussion on Present Tendencies regarding Disinfection and on House Refuse Collection.

BRITISH MYCOLOGICAL SOCIETY (at University College), at 11 A.M.—Prof. E. S. Salmon and W. M. Ware: Two Downy Mildews of the Nettle.—Dr. E. J. Schwartz and Dr. W. R. Ivimey Cook.—Life History of a New Species of Olpidium.—Symposium on the Nomenclature of "Strains": Dr. W. B. Brierley, Dr. W. Brown, Dr. G. G. Hahn, Dr. H. Wormald.

Royal Institution of Great Britain, at 3.—Sir Ernest Rutherford. The Transformation of Matter (III.).

Hull Association of Engineers (at Technical College, Hull), at 7.15.—H. J. Young. The Uses of Metallurgy in Engineering.

MONDAY, March 26.

Institute of Actuaries, at 5.—T. F. Anderson and H. O'Brien: Notes upon Experiments with Actuarial Functions and Fourier's Series.

Royal Geographical Society (at Lowther Lodge), at 5.—Prof. W. G. Fearnsides and W. H. Wilcockson: A Topographical Study of the Flood-swept Course of the Porth Llwyd above Dolgarrog.

Institute of Actuaries, at 5.—T. F. Anderson and H. O'Brien: Notes upon Experiments with Actuarial Functions and Fourier's Series.

Institution of Mechanical Engineers (Graduates' Section, London), at 6.30.—R. E. L. Maunsell: The Trend of Modern Steam-Locomotive Design (Annual Lecture).

Institution of Electrical Engineers (North-Eastern Centre) (at Armstrong College, Newcastle-upon-Tyne), at 7.—F. H. Rosencrants: Practice and Progress in Combustion of Coal as applied to Steam Generation.

Royal Society of Medicine (Odontology and Electro-Therapeutics Sections), at 8.—Special Discussion on The Pulpless Tooth.—Speakers:—For Section of Odontology: F. Coleman, C. C. Morphy, A. T. Pitts, Dr. A. Livingston, St. J. Steadman, B. Mendleson, and A. F. MacCallan. For Section of Electro-Therapeutics: Dr. H. M. Worth, Dr. G. Murray Levick, Dr. M. Jones, Dr. J. F. Brailsford, N. Grellier, Dr. A. C. Jordan, and Dr. G. B. Batten.

TUESDAY, March 27.

Royal Dublin Society (at Ball's Bridge, Dublin), at 4.15.—Prof. H. H. Dixon and T. A. Bennet-Clark: The Effect of Temperature on the Electrical Response of Plants.—W. D. Davidson: (*a*) The Rejuvenation of the Champion Potato; (*b*) A Review of the Literature dealing with the Degeneration of Potato Varieties.

Royal Society of Arts (Dominions and Colonies Meeting), at 4.30.

Royal Society of Medicine (Medicine Section), at 5.—Prof. D. W. Carmalt-Jones: New Zealand Views on Goitre.

Royal College of Physicians of London, at 5.—Dr. J. Collier: Epilepsy (Lumleian Lectures) (II.).

Royal Institution of Great Britain, at 5.15.—Prof. J. S. Huxley: The Behaviour of Animals (VI.).

Institution of Petroleum Technologists (at Royal Society of Arts), at 5.30.—Annual General Meeting.

Society of Chemical Industry (Yorkshire Section) (jointly with Hull Chemical and Engineering Society) (at Photographic Society, Grey Street, Hull), at 6.45.—Discussion on Some Aspects of the Oil Cake and Feeding Stuffs Industry.—R. A. Bellwood: Fish Meal as a Food for Cattle, Swine, and Poultry.—H. Thompson: The Analytical Aspect of the Oil and Seed Crushing Industry.—G. Milne: Oil Seed Residues in Animal Nutrition.—T. Andrews: Some Aspects of the Fertilisers and Feeding Stuffs Act.

Royal Photographic Society of Great Britain, at 7.—M. Sargant-Florence: Colour Co-ordination.

Institution of Electrical Engineers (Irish Centre—Dublin) (at Trinity College, Dublin), at 7.45.—R. B. Matthews: Electric Ploughing.

Royal Anthropological Institute, at 8.30.—Sir Arthur Keith: Human Remains discovered by Sir Aurel Stein in Ancient Cemeteries of the Taklamakan Desert.

Illuminating Engineering Society.—Discussion: Various Aspects of Street-Lighting.

WEDNESDAY, March 28.

Institution of Naval Architects (at Royal Society of Arts), at 11 A.M.—Presentation of Institution Premiums to H. J. R. Biles and W. C. S. Wigley.—Admiral of the Fleet Lord Wester Wemyss: Presidential Address.—Sir John H. Biles: The Present Position of the Question of Fuel for Ships.—At 3.—J. F. King: Bending and Loading of Ships.

Royal Society of Medicine (Comparative Medicine Section), at 5.—T. Dalling, J. H. Mason, and W. S. Gordon: (*a*) Intradermic Tuberculin Testing in Cattle; (*b*) Transference of Maternal Immunity in Sheep.—J. W. Trevan: The Present State of Knowledge of Sex Hormones.—H. J. Parish: B.C.G. Experiments in Guinea-pigs.—C. C. Okell: Diphtheria Infections and Diphtheria Immunity in Horses.

Institution of Civil Engineers (Students' Informal Meeting), at 6.30.—R. F. Legget: The Limitation of Concrete as a Material in Construction.

Institution of Electrical Engineers (South Midland Centre) (at Birmingham University), at 7.

North-East Coast Institution of Engineers and Shipbuilders (Graduate Section) (at Bolbec Hall, Newcastle-upon-Tyne), at 7.15.—J. C. Stewart: Modern Mould Loft Practice.

Society of Chemical Industry (Newcastle Section) (at Armstrong College), at 7.30.—W. E. Billinghame: Emulsions, their Scope and Application.

Merseyside Aquarium Society (at 1 Falkland Road, Egremont), at 7.30.—A. G. Thus and W. Mallinson: Demonstration of the Making of Tanks.

Eugenics Society (at Linnean Society), at 8.—Dr. F. D. Turner, Lady Askwith, and others: Segregation and Sterilisation.

C.B.C. Society for Constructive Birth Control and Racial Progress (in Grotrian Hall, Wigmore Street, W.1), at 8.30.—Debate. C. Pilley will maintain: That he agrees the Roman Catholics are right in opposing Dr. Marie Stopes. Dr. Marie Stopes will oppose.

British Astronomical Association (at Sion College, Victoria Embankment).

THURSDAY, March 29.

Institution of Naval Architects (at Royal Society of Arts), at 11 A.M.—Eng.-Capt. A. Turner: A Note on Experimental Diesel Engines.—At 12.—Presentation of Bust of the late Sir Philip Watts, by the Right Hon. Winston Churchill.—E. H. Mitchell: Design and Propulsion of Fast Double-ended Screw Vessels.—At 3.—B. L. Champness and F. McAlister: Further Notes on the Relative Strength of Fine and Full Cargo Vessels.—W. Sprague, and the Staff of the William Froude Tank: An Experimental Comparison of the Performance of Model Propellers working in Air and in Water.—At 8.—Prof. E. G. Coker: Stresses in the Hulls of Stranded Vessels.—G. H. Hoffmann: The Effective "I" of H.M.S. *Wolf*.

Royal College of Physicians of London, at 5.—Dr. J. Collier: Epilepsy (Lumleian Lectures) (III.).

Royal Institution of Great Britain, at 5.15.—Group-Capt. M. Flack: The Physiological Aspects of Flying (II.).

Child-Study Society (at Royal Sanitary Institute), at 6.—A. H. A. Gem: Physical Training in its Effect upon the Development of Children.

Institution of Electrical Engineers, at 6.—F. Lydall: The Electrification of the Pietermaritzburg-Glencoe Section of the South African Railways.

Institution of Locomotive Engineers (at 296 Vauxhall Bridge Road, S.W.1), at 6.—J. Clayton: Engine Failures.

Society of Dyers and Colourists (Midlands Section) (at University College, Nottingham), at 7.30.—Prof. F. M. Rowe: "Azoic Colours."

Chemical Society, at 8.—A. H. Dickins, W. E. Hugh, and G. A. R. Kon: The Chemistry of the Three-carbon System. Part XVII. a-cyclo-Hexylideneacetone and -methylethyl Ketone.—F. Challenger and A. T. Peters: The Nitration of Aromatic Thiocyanates and Selenocyanates.—F. Ashworth and G. H. Burkhardt: Effects induced by the Phenyl Group. Part I. The Addition of Polar Reagents to Styrene and the Behaviour of the Halogenated Ethylbenzenes.—E. B. R. Prideaux and C. B. Cox: On Selenium Tetrafluoride.

British Psychological Society (Medical Section) (jointly with Psychiatry Section of Royal Society of Medicine) (at 1 Wimpole Street, W.1), at 8.15.—Symposium on The Etiology of Alcoholism: Dr. B. Hart and Dr. E. Mapother for Psychiatry Section, Royal Society of Medicine; Dr. E. Glover and Dr. H. Crichton Miller for Medical Section, British Psychological Society.

Institution of Mechanical Engineers (Glasgow Branch).—Capt. H. P. M. Beames: The Reorganisation of Crewe Locomotive Works.

Institution of Mechanical Engineers (Cardiff Branch).—J. McCarthy: Rubber, and its Uses in Engineering.

FRIDAY, March 30.

Institution of Naval Architects (at Royal Society of Arts), at 11 A.M.—Lt.-Col. V. C. Richmond: Some Modern Developments in Rigid Airship Construction.—G. S. Baker and J. L. Kent: Experiments on the Propulsion of a Single-Screw Ship Model.—At 3.—W. G. A. Perring: The Vortex Theory of Propellers and its Application to the Wake Conditions existing behind a Ship.—J. Tutin: Cavitation.—J. L. Taylor: Statistical Analysis of Voyage Abstracts.

Institution of Locomotive Engineers (Manchester Centre) (at College of Technology, Manchester), at 7.—W. G. Smith: Some Features of the Mechanical and Electrical Equipment of the Port of Manchester.

Junior Institution of Engineers (Informal Meeting), at 7.30.—C. F. Adams: Locomotive Maintenance.

Geologists' Association (at University College), at 7.30.—A. G. Davis: The Geology of the Clapham-Morden Railway Extension.—Miss Helen M. Muir-Wood: A New Brachiopod, *Discinisca ferronae*, from the Woolwich Beds.—E. M. Venables: The London Clay of Bognor.

Institute of Metals (Sheffield Local Section) (in Non-Ferrous Section, Applied Science Department, Sheffield University), at 7.30.—Dr. W. H. Hatfield: Non-Ferrous Metals in relation to Ferrous Metallurgy.

Royal Institution of Great Britain, at 9.—Sir Ernest Rutherford: Radioactive Atoms and their Structure.

SATURDAY, March 31.

North of England Institute of Mining and Mechanical Engineers (at Neville Hall, Newcastle-upon-Tyne), at 3.—B. E. Houle: The Installation of a Booster Fan.

Royal Institution of Great Britain, at 3.—Sir Ernest Rutherford: The Transformation of Matter (IV.).

PUBLIC LECTURES.

SATURDAY, March 24.

Horniman Museum (Forest Hill), at 3.30.—Dr. E. Marion Delf: Light and Life.

MONDAY, March 26.

Gresham College, at 6.—G. P. Bailey: Modern Science and Daily Life: High and Low Temperatures.

THURSDAY, March 29.

University of Leeds, at 8.—A. N. Shimmin: Economics in Everyday Life: The Cost of Corporate Life.

FRIDAY, March 30.

Royal Institute of British Architects, at 8.15.—Dr. R. E. Stradling: "Balbus built a Wall" (Bossom Gift Lecture).

CONFERENCES.

March 26 to 31.

German Balneological Congress (at Baden, near Vienna).

March 29, 30, and 31.

Tuberculosis Society and Society of Superintendents of Tuberculosis Institutions (in Dunn Laboratory, Oxford).

March 29, at 2.—Discussion on Lupus and its Treatment.
March 30, at 10 A.M.—The Potentially Tuberculous Child.
At 2.—The Treatment of Hæmoptysis in Pulmonary Tuberculosis.
March 31.—Discussion on Intestinal Tuberculosis.

SATURDAY, MARCH 31, 1928.

Modern Thought.

APPRECIATIVE reference has been made from time to time in our columns to volumes in two comprehensive and stimulating series in which theories and problems of ancient and modern life are surveyed, and suggestive ideas are presented. In one of these series, having the general title "To-day and To-morrow," about sixty volumes have now been published, while in the other—"Benn's Sixpenny Library"—about fifty have been issued, and apparently more than five times that number are eventually to appear. It is not practicable for every addition to these series to be noticed within the limits of space which a weekly journal of science is able to devote to reviews; nevertheless, we are glad to direct especial attention to the two series, because of the number of volumes in them dealing with scientific and other aspects of modern civilisation.

If the function of literature is to unify life and to show men its meaning, "Benn's Sixpenny Library" is a definite contribution to literature. It is also a distinct refutation of the suggestion that cheapness and nastiness are necessarily synonymous. Moreover, it is not an exaggeration to say that the series comprises, in clearly printed and useful form, the most interesting and advanced thought of to-day. The volumes on the atom and on relativity are typical examples of how modern scientific developments can be written so that he who runs may read. Through the whole range of the series there is clearly discernible the thread which binds human knowledge together in significant unity. Whatever may be our view of religion, either as divine inspiration or as mere guesswork concerning our origin and destiny, here are outlines of the great systems which have influenced, and are influencing, the world. Here, too, so that we may understand and pardon even those tendencies and qualities which may appear most unpleasing to us, are historical sketches of Italy, China, India, and Russia.

While, however, it is to history and religion that we may look for causes and explanations in the sense that we would examine more material environment, it is in that mirror of their laughter and tears and their strivings and failings which ordinarily we call literature, that we shall find presented the real character of a people. English, French, and Russian literatures form, therefore, an important part of the series. Intermingled with, growing out of, and in turn guiding all these expressions are the trades by which we live and the political and economic ideas by which we are governed. None is wholly neglected. The books, therefore, give us a broad vision of human life investigating and modifying its environment, spinning its theories of life and death, recording its ambitions and its disappointments, and dreaming its dreams of the ultimate beauty it so blindly seeks.

The extraordinary progress made by science in increasing our control over Nature has been conditioned and deeply marked by an inevitable trend towards specialisation. More and more we come to see that, while specialisation is essential, it is full of danger. More and more power is placed in human hands, but those who discover that power frequently pay little attention to the ways in which it will be used. They have little time to observe what their fellows are about, and they have still less time to peer into the future and to attempt to visualise the kind of world their united efforts are making; and yet their responsibility as members of a civilised community is enormous. They would hesitate to present a bottle of nitric acid, prettily yellow and delectably fuming, to a nursery full of small children; but they offer equally dangerous gifts to an equally primitive world.

While these absorbed specialists may be so oblivious of the tremendous significance of their tasks, the confused, sprawling, and self-cancelling thing called public opinion is just as uninformed concerning the world which might be made out of such devoted labour. Neither man of science nor layman has the time or the opportunity fully to follow the intricacies of civilisation's myriad activities, and to form any adequate conception of where they are all leading.

It is not too much, therefore, to say that the "To-day and To-morrow" series (London: Kegan Paul and Co., Ltd., 2*s*. 6*d*. net each volume) is aptly named and fulfils a definite need. The books are not ponderous tomes crammed with the hieroglyphics and sometimes incomprehensible jargon of a jealously guarded technique. They are small, well printed, and deal in fascinating sweeps with what may yet be our destiny. It is difficult to select from them, but separate notices of several have already appeared in our columns: of those now before us, we would especially indicate the three which deal with the future of the Press, of Labour, and of Government. Upon the development of all three rests the attainment or otherwise of the dreams and aspirations of both scientific worker and layman.

Tempests and Man.

Great Storms. By Carr Laughton and V. Heddon. Pp. viii + 251 + 13 plates. (London: Philip Allan and Co., Ltd., 1927.) 10*s*. 6*d*. net.

WITHIN comparatively recent times, the calculating wisdom of man has progressed far in the process of rendering Nature innocuous in her evil moods; so far, indeed, that legends declaring her majesty and portraying man trembling on his own hearth, the sport of elements which he cannot restrain, are rapidly going out of fashion. A materialistic age is satisfied to substitute formulæ proving that Nature's latest gesture is only such another trick as might have been expected, and to devise rules by following which we may so fortify ourselves structurally as to give her only a remote and local chance of being dangerously unpleasant.

The shearing of romance and healthy superstition from Nature is to be regretted. Security for its own sake is not a good thing, and in Great Britain we have lately so far magnified our own importance in the universal scheme of things that an unduly wet summer fills the whole community with unrighteous indignation, and the overflowing of the Thames is considered not so much an act of God as a breach of faith on the part of the Government.

The present volume, which reverts to more romantic days, is welcome. It is beyond hope that it will fill the breast of the modern reader with that humility which was wont to be born in the wake of storms of old, but at least it will confirm what Nature is capable of doing, and what, in spite of man's ingenuity, she continues to do in those 'foreign parts' which are the special target of her fury.

As might be expected, the book has a strong flavour of the sea. Familiar titles appear among the twelve chapters—"Armada Gales," "The Last Voyage of the *Elizabeth*," and "After Trafalgar"; but the recounting of these naval epics by authors who are obviously well qualified to speak both for the sailor and the meteorologist is well worth while. What the large and then unknown factor of wind meant to the sailing ships of England, Spain, and Holland in their struggle for sea supremacy is described in vivid narrative, although to the landsman, inclined to be impatient with an era when ships of the line resembled in shape alone the giants of to-day, the authors may appear to have been so liberal with nautical detail that the main theme is from time to time submerged.

Reading of the unceremonious interventions of the Storm King who in Armada days frequently converted a promising naval engagement into an ignominious *sauve qui peut*, we are led to speculate on the might-have-been in a less windy and weather-beaten world. A very interesting and instructive chapter—"Storms in History"—rather favours the opinion that the course of political development from the earliest civilisation has been oriented in a very minor degree, if at all, by tempests of whatever variety. This very debatable point is not now likely to be decided. It would be a fascinating research, however, granted a long enough span of life, to work out a probable map of the world based on the assumption that Noah had not been incommoded by a flood, or that fine and not stormy weather prevailed when certain historical battles [illegible]re fought, or that, say, less vigorous convection [illegible]btained at the time when hailstones resulted [illegible] Treaty of Bretigny. Unfortunately, the [illegible]vere storm on air navigation does not [illegible]cope of the book. Remembering [illegible]ilure of a Zeppelin raid — a [illegible] in a negative sense—we [illegible]s may yet make history. [illegible]ccount of what is rated the [illegible]enced in the British Isles, [illegible] There seems to be every [illegible]storm does take pride of [illegible]ppier in our estimate if [illegible]mething resembling a [illegible]ailable to curb the overwrought imagination of the sufferers. The centre of that storm passed near to Liverpool. Lately, as a culmination of the furious gales already recorded in 1928, the wind at Liverpool attained a speed of 104 m.p.h., but this latter-day gale is unlikely to receive more than an honourable mention. It may be that the surface obstacles to-day are too many and too stout to give the wind a fair chance. However, the storm that introduced Addison to fame and incited Defoe to count 17,000 trees blown down in Kent, certainly merits a place in history.

In chapters dealing with the West Indian hurricanes, the China Seas typhoons, and the world's "Windy Corners," the meteorology of the winds is happily blended with descriptive narrative. An illuminating account of the Tay Bridge disaster and of the subsequent inquiry finds a suitable place. The theme is varied by a chapter on historical volcanic storms, in which Nature's most awe-inspiring and most destructive efforts are presented in realistic language.

A lighter note is struck in the final subject—winds and superstitions—an engrossing chapter on those mythological associations which for centuries have exercised the force of religion on the mind of the seaman.

The book adds the advantage of historical fact to the entertainment of a novel, and will make a general appeal. The meteorologist will find much of special interest and, incidentally, a vindication of his own calling if such were needed nowadays; for whereas to-day, with ships hundreds per cent. more seaworthy, weather reports and gale warnings are considered indispensable to navigation, it appears that the conservative skipper of Piddington's time, rather than accept that gentleman's Law of Storms and sail for safety, frequently sank both his pride and himself in a cyclone.

The prevalence of January and February in the dates associated with historic storms, and the fact that the worst damage could nearly always be attributed to the venom of a 'secondary,' suggest that, meteorologically, 1928 has upheld tradition. In the light of recent happenings, particular interest attaches to the reference to flood tides on p. 6, where the authors' remarks on the chance of a northerly gale driving water into the cod of the North Sea to cause a Thames flood seem to have been prophetic.

A uniformly high literary standard is combined with popular treatment and a wealth of detail which is highly diverting. The general presentation is excellent and the illustrations are well chosen. Mr. Cecil King, R.I., may have taken a rather rough view of the sea; but his drawings convey the required impression, and in the circumstances few will be found competent to offer authoritative criticism.

E. TAYLOR.

Physiology in Great Britain.

History of the Physiological Society during its first Fifty Years, 1876–1926. By Sir Edward Sharpey-Schafer. Pp. iv + 198. (Cambridge: At the University Press, 1927.) 15*s*. net.

THIS "History of the Physiological Society" has been written by its only surviving and still active original member, Sir Edward Sharpey-Schafer, who undertook it as a labour of love, and has succeeded in presenting a wonderfully attractive account full of biographical details and human touches. The thumb-nail sketches of deceased members are illustrated by small portraits let into the page in the position of an illuminated initial letter; many of the photographs of the earlier members present them with a youthful appearance unfamiliar even to those who are now of an age when superannuation and retirement are in the near offing. The notices themselves have the charm conveyed by personal knowledge and kindly humour: thus, "Foster's success was, however, not due entirely to his influence over the younger Cambridge biologists (Gaskell, Balfour, Langley, Newell, Martin, and Sheridan Lea), but quite as much to the power he had of influencing senior members of the University, who were not long in recognizing that a prophet had arisen amongst them who would make the bones of biological science, which had become very dry in Cambridge, live again." The occasional reproduction of signatures at meetings and dinners adds a further interest to what is, among other things, a dictionary of physiological worthies.

This story of the Society and its members, with a general record of its scientific activities, begins by showing how British physiology, which in the middle of the nineteenth century was far behind that of France and Germany, began to rise to its present high position. Prof. William Sharpey (1802–1880), anxious to improve the teaching of physiology at University College, London, enlisted Michael Foster's services as professor of practical physiology; this appointment of "the actual begetter of the Physiological Society" was pregnant with importance to the future of physiology in England. In 1870, Foster went to Trinity College, Cambridge, as prælector in physiology, and Burdon-Sanderson took his place at University College, succeeding Sharpey in 1874.

The conception of the Physiological Society two years later was primarily the result of the antivivisection agitation, an example of *Ex malo bonum*. Its object as defined in the first rules was to promote the advancement of physiology, and to facilitate the intercourse of physiologists, which it has done in a remarkable manner by providing opportunities for preliminary discussion and helpful criticism of work and the formation of pleasant friendships. The influence thus exerted by intimate personal contact and overcoming the disadvantages inherent in the otherwise inevitable system of work in the lonely furrow must obviously have been most valuable. Michael Foster's genial personality was a great asset in bringing together workers not only in Great Britain, but also from abroad, and as bearing on this, Sir E. Sharpey-Schafer's account may be quoted of Foster, when president of the British Association at Dover in 1889, welcoming and saluting *more gallico* the president of the corresponding French Association.

Among the founders of the Physiological Society were George Henry Lewis, who, with George Eliot, was concerned in the establishment of the prælectorship in physiology at Trinity College, Cambridge, Francis Galton, William Bowman, T. H. Huxley, F. W. Pavy, W. H. Gaskell, F. M. Balfour, Gamgee, Klein, Langley, and G. J. Romanes, who, at one time intent on taking orders, veered round to entire scepticism, and eventually returned to religious orthodoxy. A very important outcome of the Society's enthusiasm was the *Journal of Physiology*, which, largely by the liberality of the late A. G. Dew-Smith, was started in 1878 and first edited by Foster; it was taken over in 1893 by J. N. Langley, who also became its proprietor and was a model editor until his lamented death in 1925, when the financial responsibility was resumed by the Society, and an editorial board of f [illegible]
members, with Sir Charles Sherrington as cha [illegible]
was appointed.

At the end of 1880, the most imp [illegible]
of the Society—the special aftern [illegible]

Proceedings of the Ph [illegible]
munications which me [illegible]
Journal of Physiology. These *Proceedings* show that all important advances in physiology made in Great Britain during its existence have in the first instance been brought before the Society, and thus form a record of which any society might be proud.

The Kinetic Theory.

Statistical Mechanics with Applications to Physics and Chemistry. By Prof. Richard C. Tolman. (American Chemical Society Monograph Series.) Pp. 334. (New York: The Chemical Catalog Co., Inc., 1927.) 7 dollars.

THE younger generation is not infrequently reproached with lack of respect for its scientific fathers. The complaint is probably unfounded, but, even if it were a just one, the younger chemists at least might plead that they had in some ways been set a bad example. The atomic theory is the keystone of chemistry: two generations ago the mechanics of atoms and molecules was worked out with the very minimum of assumptions which increasing knowledge might invalidate, but the results

vement were more or less ignored
Only now are the kinetic theory
t. ethods coming into their own;
his nch of knowledge is a peculiarly
one. Nearly everyone, with or without
philosophical reservations which his atti-
rds the theory of knowledge may dictate,
the existence of molecules which move
ıe way exert influences upon one another.
even idealists will admit that within the
nfines of scientific realism a certain
may be achieved by introducing a quan-
l energy. Statistical mechanics, which
means of determining such important
the distribution of energy among mole-
l its rate of transfer, without intimate
of the nature of molecular interactions,
ificent compromise between the rather
ticism of thermodynamics and that kind
iled theory which at present would be
and doomed to failure.

olman's book contains both a systematic
of the principal results of the kinetic
d an account of many applications. It
m most other books on the subject in
ecial prominence to the discussion of
reaction velocity.

nethods of treatment are possible: the
f statistical mechanics in its classical
exposition of which is the first object of
is the most general, and in many ways
rigid and fruitful, but it is, of course, not
abstract. The important statistical laws
times more easily derivable in special
erhaps for this reason the book may appeal
hysicists interested in chemical problems
emists anxious to equip themselves with
tant weapon. However, the first two
begin at the beginning: and in Chap. ii.
a brief treatment of general dynamical
, including Lagrange's function and
's equations. This part would be made
re useful by a little illustrative expansion.
ird chapter deals with phase spaces, en-
and Liouville's theorem. The ergodic
is is discussed in an interesting way—
ıg that physical intuition can seldom be
l with in mathematical physics. In the
three chapters the Maxwell-Boltzmann law
l and applied. Points of special interest
he discussion of the approximation involved
ucing Stirling's theorem, an illuminating
of deviations from the most probable dis-
, and a neat treatment of equipartition.

The remaining eighteen chapters are grouped by the author under the headings: Introduction of the quantum theory; application to molecular processes; the rate of physical-chemical change; and conclusion.

One of the most pleasing things about the book is the amount of actual physical and chemical information contained in the sections devoted to the applications of the fundamental method. The style is lucid, and there is a welcome frankness about underlying assumptions. Nothing makes for obscurity more than their surreptitious introduction, the reader being left to infer a logical necessity. The Einstein treatment of radiation is, for example, often given in a very puzzling form. Tolman, in the course of an excellent section on radiation, discusses clearly the nature of the assumptions made in introducing the two emission coefficients.

A great chemist once said "Physical Chemistry is all very well but it does not apply to organic substances." On p. 152, Prof. Tolman is to be observed giving the chloroform molecule three hydrogen atoms and one chlorine atom—without invalidating his argument; which is something of a *revanche*!

Research in the Cotton Industry.

Research in the Cotton Industry: a Review of the Work of the British Cotton Industry Research Association up to the end of 1926, carried out under the direction of the late Dr. Arthur William Crossley. Edited by Dr. Robert H. Pickard. Pp. xv + 80 + 10 plates. (Manchester: Shirley Institute, 1927.) 5*s*.

THIS book is a very readable report of five years' progress in industrial research carried out by the British Cotton Industry Research Association under the direction of the late Dr. A. W. Crossley, and may be considered as a memorial and tribute to him, who devoted the last days of his life to one of the most arduous of tasks, namely, the focusing of scientific talent on the problems of an industry in which the field of such endeavour is anything but clear.

The chief difficulty with which the industrial, as distinct from the academic, research worker has to contend is the suitable propounding of the result of his work; for not only must he provide a complete record for the benefit of other workers on his subject, but he must also endeavour to see that in some way the practical information made available may be comprehensible to the non-scientific industrialist. Unfortunately, these two objects cannot easily be reconciled, as each requires its own particular treatment, and compromise is practically impossible. Hitherto, the Shirley Institute memoirs have taken the form of scientific papers, and those who have read the publications of them in the *Journal of the Textile Institute* will no doubt appreciate the difficulty experienced by the layman in picking out the salient points of such reports, cloaked, as they must be, in scientific terms, and written in a precise but, to him, somewhat dull manner. The language of the research worker is not the language of the man in industry. The need, therefore, has been for what one might call a 'popular' exposition of the results achieved in connexion with the various problems that have been tackled; and the book under review satisfies this need in a most successful manner, and is a credit to those responsible for its publication.

In the introduction reference is made to various special cases of difficulty which have been successfully dealt with, and it is at once made clear what a very large field of fundamental research has had to be covered. Two of the most important factors governing the quality of textiles are uniformity and consistency, and it is natural, therefore, that a considerable amount of time should have been given to determining to what extent the shortcomings in these respects can be attributed to the raw material itself. The physical and chemical characteristics of a great variety of cottons have accordingly been investigated (Chap. i.), and, in addition, problems appertaining to bacterial and fungal infection during conditioning have been tackled

The researches in spinning and doubling (Chap. ii.) have been largely devoted to studies of the effect of various processes on the physical properties of the products, and attention has also been given to devising improved methods of carding and drafting.

Good sizing is of very great importance to the weaver and to the finisher, and has received its fair share of attention. Reference is made (Chap. iii.) to investigations carried out to determine what factors influence successful treatment of the material, and how the danger of mildew infection can be reduced to a minimum.

Chap. iv. may disappoint some because of its brevity; but the Association appears, rightly, to have deferred work on weaving proper until the fundamental properties of cottons and yarns have first been systematically studied. Even so, it is recorded that work on the problems of the manufacturing section of the industry is now in hand, and would seem to give promise of some interesting results.

Chaps v., vi, and vii. refer to researches on bleaching, dyeing, and finishing, among which might be mentioned those on the loss of weight in scouring, the removal of oil, rust, and other stains; the causes of tendering during bleaching; the effect of mercerisation on hair dimensions; the effect of variations in raw material on its reaction to dyeing and finishing; and on the schreinering process.

In Chap. viii. are described some of the instruments that have been designed and made at the Institute to enable the work outlined in this book to [illegible] prosecuted.

W. E. Morto[illegible]

Our Bookshelf.

Flora of West Tropical Africa: the British [illegible] African Colonies, British Cameroons, the F[illegible]ch and Portuguese Colonies south of the T[illegible] of Cancer to Lake Chad, and Fernanda [illegible] By J. Hutchinson and Dr. J. M. Dal[illegible] Prepared at the Herbarium, Royal Botanic Gardens, Kew, under the supervision of the Director. Published under the Authority of the Secretary of State for the Colonies. Vol. 1, Part 1. Pp. x + 246. (London: The Crown Agents for the Colonies, 1927.) 8*s*. 6*d*.

This new work, the result of the collaboration of two officers of the Kew Herbarium, will be very welcome to all interested in the flora of west tropical Africa, as well as to systematic botanists in general. In its handy form it will be in greater daily use by the field worker in that region than the monumental "Flora of Tropical Africa," indispensable as that work is for reference. The area covered is a wide one, and includes not only British possessions and mandated territories, but also some administered by the French and the State of Liberia

The present part contains the Gymnosperms (two only) and rather more than half the families of the Dicotyledons. The systematic arrangement adopted is that devised by one of the authors, Mr J. Hutchinson, which was published in 1927 in his book "The Families of Flowering Plants." The system is explained in a brief note on p. 42, and its sequence displayed on pp 43 and 44.

The descriptive part has been condensed by adopting the arrangement, already in use in several similar works, of descriptive keys for the genera and species This is a convenient method for the field worker and has the merit of saving space, a very desirable quality in unsettled countries where transport facilities are lacking. The value of the work is greatly enhanced by about a hundred excellent detailed figures illustrating the most typical plants of the more important genera. Some of these are from drawings by Mr. Hutchinson, but the majority are the work of Mr. W. E. Trevithick.

An outline map indicates the area comprised Several pages of the preamble are devoted to an interesting record of botanical exploration in the several countries included, and it also offers a comprehensive bibliography. Finally, one is thankful for a handy glossary of botanical terms illustrated with a number of illuminating figures.

The key to the families is entirely artificial, and follows that, now becoming familiar, devised by Mr. Hutchinson and employed in his earlier work already referred to above.

C. E. C. F.

La question eugénique dans les divers pays. Par Dr. M. T. Nisot. Vol. 1. Pp. 513. (Brussels: Librairie Falk Fils, 1927.)

DR. NISOT has had the useful idea of collecting all the available information on eugenic activities and tabulating it by countries. The present volume contains the information for Great Britain, the United States, and France, and is introduced by a comprehensive historical sketch. Volume 2 is promised shortly, and will include the facts for most other nations.

The author has, it must be confessed, thrown her [illegible] rather widely. Not only does she include eugenics in the usually accepted sense of attempts to improve the germplasm of the race; not only birth-control, and the regulation of immigration, which both obviously can have potent effects for good or for evil upon that germplasm; but also all sorts of activities devoted to improving the health and conditions of the individual, such as organisations for combating venereal disease, tuberculosis or alcoholism, the education of mentally subnormal children, infant welfare centres, and so forth. It seems a pity that these were included. For one thing, they have no direct eugenic bearing in any proper sense of the word, and for another, if they are included, why are not all organisations aimed at ameliorating the conditions of life included? Venereal disease, in spite of the possible transmission of the causative agent to the offspring, is not an affair of eugenics, but of public health; and if the education of mentally deficient children is included, why not education in general? As matters stand, the presence of these sections in the book only confuses the issue.

On the side of eugenics proper and of the associated topics of birth-control and immigration control, however, the book will be found very useful. It is extremely desirable to have such sources of information available. The historical account for each country, though brief, is valuable; and nowhere else in convenient form will be found a statement of what organisations exist in each country.

O povaze věcí. Napsal Sir William Bragg. Přeložili Prof. Dr. Antonín Šimek a Dr. Hannah Šimková-Kadlcová. Pp. 136 + 32 tabulky. (Prague: Jednota Ceskoslovenských matematiků a fysiků, 1927.) Kč. 22.80.

OF the three Czechoslovak universities, those at Prague and Brno possess faculties of science. The University of Prague dates from 1347, but the Masaryk University of Brno, at which Dr. Šimek is professor of physical chemistry, was only founded after the War. It has therefore no traditions, and before schools of research are established it has been necessary for such leaders as Prof. Šimek to inculcate the spirit of scientific inquiry both by their academic lectures and by presenting the students with a literature in their own language.

Instead of writing a new book, Prof. Šimek has elected to translate Sir William Bragg's "Concerning the Nature of Things," which was the subject of his Royal Institution juvenile lectures in 1923. These lectures, Prof. and Mrs. Šimek point out in the preface to their translation, were inaugurated by Michael Faraday, and are models of approaching the subject to young minds since they retain and stimulate scientific accuracy. The high standard set by Faraday, for example, in his "Chemical History of a Candle," has been maintained by his successors, and Prof. Šimek was so impressed with the inspiration to be derived from those by Sir William Bragg that he decided to translate the book for the benefit of his own students.

Of additional interest is the fact that the last chapter on the nature of crystals deals with the results obtained by Sir William and Prof. W. L. Bragg in their X-ray studies of crystal structure. Prof. Šimek enthusiastically compares the lectures to Lucretius's poem "De rerum natura," with the important difference that the present work is no idle fantasy, but rests upon the sure foundation of scientific fact.

J. G. F. DRUCE.

Elementary General Physical Science. By W. R. Jamieson. Pp. xi + 63 + 88 + 147 + x + 16 plates. (Melbourne and London: Macmillan and Co., Ltd., 1927.) 8*s.* 6*d.* net.

'SCIENCE for All' is the reaction against undue specialisation in the schools, but there is the danger of making the subject so discursive that it ceases to be science. Mr. Jamieson's attempt to provide a broader survey of science for Australian schools consists in the main of an account of some of the great discoveries in chemistry, physics, and astronomy, with adequate and interesting historical details; while every opportunity is seized to introduce pieces of information. Thus, thirty-seven pages on energy include the spectrum, voltaic cells, Gay Lussac's law of volumes, oxidising agents, hydrocarbons, isomorphism, magnetism, galvanometers, dynamos, radium, lenses and telescopes, and end with the periscope of a submarine. While much can be said in favour of such a course, we suggest that to sacrifice depth of culture to obtain breadth is not a scientific method of producing a good harvest.

Chemistry. By W. H. Barrett. (Clarendon Science Series.) Pp. viii + 151. (Oxford: Clarendon Press; London: Oxford University Press, 1927.) 5*s.* net.

MR. BARRETT'S book gives a clear account of some of the simpler chapters of chemistry, with indications of their bearing on everyday life. There is a good chapter at the end on the modern theory of atomic structure. The book is suitable for the general reader who wishes to obtain some idea of modern chemistry.

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Liquid Stars and Atomic Volume.

THE problem of the general state of matter at high temperature is so fundamental in stellar physics that I venture to pursue the discussion with Dr. Jeans (NATURE, Feb. 25, p. 278). I would first thank him for his reply to my letter, which, though I differ from it on a number of points, deals fairly with the questions raised. I still believe I was not exaggerating in saying that Jeans's theory requires that the ions (in giant *M* stars) should be so large that they jam at densities $\frac{1}{16}$ that of air. Jeans wishes to amend this to 80 × air. But my figure represents the order of magnitude of the central density of Betelgeuse according to the usual gas model, and he has himself said that the star contracts as a gas until there are substantial deviations from the gas laws in the central regions. To form his liquid core of higher density it would seem that Betelgeuse must have contracted as a gas to $\frac{1}{10}$ its present radius, and then for unexplained reasons thrown out a gaseous envelope filling the present volume. Or starting from his liquid core of density 80 × air, we have to face the problem of balancing on this a gaseous atmosphere containing much less mass and subject initially to 8000 times the gravitation of the ordinary model. I think that to achieve this Dr. Jeans will have to depart much more widely from current theory than he intended.

Again, Dr. Jeans favours the hypothesis that long-period variables are pulsating stars. Like others, he finds this supported by the relation of period to density. It is well known that the periods and densities fit approximately if the usual densities are accepted; but the agreement will not be maintained if the dynamical behaviour is determined by a liquid core of density 8000 times greater. The high density and comparative incompressibility would make the period much too short.

Accordingly, I do not give up my point that Dr. Jeans requires the ions to have diameters 50 times greater than the ordinary neutral atoms. For the rest of this letter, I am content to accept his own estimate of diameters 50-80 times the diameter of the electron system in the Bohr model, which he agrees is "a bit perplexing," but will not admit as "certainly wrong." May I protest that the words "certainly wrong" were not used in this connexion in my letter? They were applied to one of his defences (or suggestions) beginning with "we might, in any case, expect," referring therefore to current knowledge and not to unforeseen developments of atomic theory. The expectation was one which would seem very plausible to most readers, who naturally think that the classical electrostatic repulsions between the ions, by tending to prevent unduly close approaches, have effect equivalent to atomic volume. When, however, the attractions between ions and electrons are included and the whole correction to the pressure is calculated according to the general methods (set forth clearly in Jeans's "Dynamical Theory of Gases"), it is at once found that the electrostatic forces actually give the reverse effect to atomic volume. The material accordingly remains as compressible as (or more compressible than) a perfect gas until the density is so great that non-classical reactions become important. There we come to more doubtful ground, but the general cause of the atomic volume effect in ordinary gas seems fairly clear. It is not the ions, but the bound electrons which set a limit to the packing. One quantum orbit or one unit cell of phase-space is required for each electron. With increasing density the cells become filled, and ultimately we should be unable to proceed further without squeezing electrons out of the material. Alternatively, if the electrons are endowed with high energy extra cells of phase-space corresponding to high velocities become available, and the congestion is relieved. In this way high temperature obviates the congestion that gives rise to atomic volume effects.

With ions distant 50-80 times their own diameter and any number of intervening quantum orbits lying vacant, there is no approach to the congested condition. I think that a quantum physicist confronted with such a problem would not hesitate to treat it by classical perturbations in accordance with the Correspondence Principle. Dr. Jeans seems to be demanding something which goes against not the details, but the broadest principles of the quantum theory. Even the broadest principles may of cour[illegible] need amendment, and it would be rather pleasin[illegible] astronomical results were definite enough to d[illegible] amendment; but I have devoted part of my former letter to challenging Jeans's argument that considerations of stability make the liquid star theory *compulsory*. To my mind the main interest in the theory of the constitution of the stars lies in connecting the laws and conclusions reached by physicists with those discovered in astronomy; if once we begin modifying the former, the investigation loses definite aim and takes on a speculative character. If a new astronomical theory provides its own rules for atomic volume, it may equally well provide its own rules for the absorption coefficient, etc.

With regard to the significant features of the Russell diagram, which Jeans believes to be explained by his theory, I admit his counter charge that I am waiting for something to turn up. It is possible in cosmical theories to be too precipitate.

A. S. EDDINGTON.

Observatory, Cambridge,
Mar. 7.

I CAN only adhere to my original views as to atomic diameters. Prof. Eddington tries to challenge my position by arguments based on "the usual gas model." By this I think he means his own gas model, which is of a very special and restricted type, and by no means characteristic of the general gaseous configurations of a star. I believe his difficulties arise solely from the defects of his own model.

Eddington's model is developed from the assumption that the generation of energy per unit mass *G* is connected with the coefficient of opacity *k* by the relation

$$G = \frac{1}{\rho r^2}\frac{d}{dr}\left[\frac{1}{k}\int_0^r \rho r^2 dr\right] \times \text{constant}.$$

This seems to me an extraordinarily artificial relation. As Russell has repeatedly pointed out, it makes *G* violently negative in the outer layers of the star, so that these re-destroy the energy created in the inner layers, only a small balance escaping from the star as radiation. I think I am right that the reason why Eddington adopted this surprising value for *G* was merely that it makes the equations integrate out with amazing ease—in fact, just like a Tripos problem.

When this special value for *G* is discarded, the problem of gaseous stars becomes far more complex. I have given partial solutions in the *Monthly Notices of the Royal Astronomical Society* (1925 and 1926), and a fuller solution appears in a book, "Astronomy and

Cosmogony," shortly to be published. Eddington's model gives a central density uniformly equal to 54·4 times the mean density. My general solution shows that with energy generated fairly uniformly throughout the star's mass, this factor is increased to anything from 88 to infinity, according to the star's mass. A very rough calculation (*Mon. Not. R.A.S.*, **87**, p. 40) gave the central density of a gaseous Betelgeuse as 2, or 1600 times that of air, as against the $\frac{1}{100}$ that of air given by Eddington's model. This was before I was contemplating liquid stars, and I was worried to find that the density was inconsistent with the gas laws being obeyed. I lay no stress on the actual value; indeed, other calculations have given 0·1 and 0·04. My point is that when the special restrictions of Eddington's model are discarded, his dynamical case against liquid stars disappears. No gaseous envelope need be "thrown out," for it is already there in a gaseous star with any reasonable generation of energy, and is 'balanced,' not only against 8000 times but even against 160,000 times the gravitation of Eddington's restricted model.

The high central density is a consequence of the large mass of Betelgeuse. If Eddington had produced a star of low mean density and small mass, I could not have met his objections. It is, I think, significant that no such stars exist. The theory of liquid stars explains that such stars cannot exist, because they would be unstable, and so accounts for the observed gap between giants and dwarfs.

Similar considerations apply to the long-period variables, since these also are very massive. The density is more uniform in a liquid star than in a gaseous star, so that the period–density law is better obeyed. I think that Eddington's argument as to "dynamical behaviour" contains a further fallacy, as can be seen by passing to the limiting case of an incompressible core of high density; the pulsations become purely atmospheric and have long, not very short, periods.

I agree with Eddington about the electrostatic forces and quantum dynamics. I never meant, however, to suggest that, other things being unchanged, rising temperature could increase effective diameters. What I had meant to suggest, as a conjecture, was that, as successive ionisations occurred, it might increase the ratio of effective diameter to Bohr-diameter, this being all I needed. I am sorry if I did not make this clear. If, as I think, stability considerations rule out gaseous stars, then all this becomes unimportant; the theory of liquid stars is also freed from the speculative taint Eddington sees attached to it. Indeed, it becomes the obvious high road of progress, as is also suggested by the fact that stars break up under rotation in the manner of liquids, not of gases.

J. H. JEANS.

A New Injection Mass—Rubber Latex.

THE principle applied in the utilisation of rubber latex as an injection mass is the fact that the latex of the rubber tree—*Hevea brasiliensis*—coagulates to form rubber in the presence of dilute organic acids such as acetic or formic. After tapping the rubber tree, the collected latex may be preserved in a fluid condition by the addition of ammonia, and I believe it is exported from Ceylon preserved in this way. The latex which I used in my first injections was obtained more than three years ago, when ammonia to the extent of 5 per cent. was added to it, and although, standing so long, it had become creamy at the surface, it regained its normal fluidity on shaking. Latex is of the consistency of milk, so no difficulty arises in its introduction into blood-vessels or its penetration into the finer capillaries.

It is advisable to wash the blood out of the vessels of a newly killed animal with normal saline to which a trace of sodium bicarbonate has been added. The latex may then be injected with a syringe, glass injection-pipette, or in the case of small animals with a hypodermic syringe. When the injection is complete the canula or needle is withdrawn from the vessel, and a drop of acetic acid on the wound will close it with a clot of coagulated rubber. Also, if any small vessels have been cut in the preliminary dissection to expose the vessel for injection, bleeding can be stopped by sponging the cut part with acetic acid. The injected fluid is converted into rubber on the immersion of the animal in dilute acetic acid, which quickly penetrates the tissues and coagulates the latex. Although general coagulation commences so soon as the latex is acid to phenolphthalein, it is not complete until there is a slight excess of acid; and I find that in the case of whole animals the process is hastened by pouring 20 per cent. acetic acid into the body cavity. In this way the fluid mass is converted into an elastic solid, which, even in the smaller vessels, possesses amazing strength and elasticity.

If pure latex is used the resulting injections are white, but better results may be obtained by using it as a vehicle for different colouring masses. Carmine dissolved in ammonia and added to the latex gives very good results. Prussian blue becomes grey when mixed with ammoniacal latex, but regains its blue colour when the acid is added for coagulation. Specimens injected with Prussian blue are best preserved in spirit, for the colour tends to transude in formalin and stain the surrounding tissues. Methyl blue gives good results, but methylene blue and methylene green cause coagulation of the latex. As latex is not a viscous fluid, the use of solid precipitates such as French blue, red-lead, or mercuric iodide as colouring masses presents difficulties, for if much precipitate is added the physical action of the finely divided solid causes coagulation, and if a little is added it quickly precipitates itself, either before use or to one side of the blood-vessel. These difficulties may be overcome by adding glycerine to the latex. One volume of glycerine to three or four of latex gives a medium sufficiently viscous to prevent rapid sedimentation and of a sufficiently high rubber content. The colouring mass should be mixed with the glycerine first, and this mixture stirred into the latex.

The following are a few of the formulæ I have found useful:

Carmine Latex Mass.

Carmine	2 gm.
Ammonia	5 c.c.
Water	5 c.c.

Break the carmine up to a fine powder in a mortar and add the ammonia and water, stirring until a dark but clear solution is obtained. 1 c.c. of this carmine solution should be added to every 30 c.c. of latex required, and an injection mass is obtained which will keep indefinitely. I find this the most useful injection mass.

Methyl Blue Latex Mass.—5 c.c. of a 2¼ per cent. solution of methyl blue in water should be added to every 25 c.c. of latex. The injection mass is of a pale blue colour, but becomes bright on the addition of the acetic acid.

Prussian Blue Latex Mass.

Prussian Blue	1 gm.
Glycerine	5 c.c.
Latex	25 c.c.

Prepare Prussian blue by adding a strong solution of ferric chloride gradually to a concentrated solution of potassium ferrocyanide, filter the precipitate through fine silk, wash in water, and dry. 1 gm. of the dry solid should be ground up in a mortar with 5 c.c. glycerine, which mixture should be stirred into the latex

My preparations have been mainly of those vertebrates used in my practical classes—frogs, lizards, pigeons, and rats, and one invertebrate which I injected —*Achatina fulica*, the giant African land snail—made a successful preparation. Prof. A. G. Smith, professor of anatomy at the Ceylon Medical College, assisted me in the injection with carmine-latex of a human fore-limb which had been previously injected with formalin by the method usually adopted for such subjects. He has dissected the preparation and finds that the latex injection shows up the vessels as well as the ordinary red lead method, with the additional advantage that the smallest vessels can be dissected to their ultimate distribution without breaking. On account of the formic acid present in commercial formalin, specimens which can only be injected after preservation should be preserved in non-acid formalin, prepared by the addition of 5 gm. borax to every litre (W. R. G. Atkins, *Jour. Marine Bio. Ass.*, **12**, No. 4, 1922).

A few of the advantages of this technique are the following: There is no danger of solidification of the mass before the injection is complete, as so often happens with warm injection masses; the injection mass does not extravasate; the vessels are strengthened without rigidity, allowing an extensive dissection or exploration after injection; and, even if the walls of the vessel are damaged in the subsequent dissection, the solid rubber core of the vessels remains From one point of view this method is like de Fol's metagelatin method, but coagulation is much easier with latex, and the resulting rubber is strong and elastic. It does not appear to be applicable to material for sectioning, but I have found it ideal in the preparation of museum specimens, for class demonstrations, and ordinary dissections of vascular systems.

I have to thank Mr. E. C. de Fonseka, Colombo, for supplies of latex, and also the Rubber Research Scheme here for latex, and in particular its chemist, Mr. T. E. H. O'Brien, for information regarding coagulation. He says, regarding supplies of latex, that it is doubtful whether there are any general importers into England, except to fulfil specific orders, but he thinks that the Rubber Growers' Association, Incorporated, 2 Idol Lane, Cheapside, E.C 3, would be willing to supply or arrange for supplies for experimental purposes.

Ceylon University College,
Colombo, Feb. 22.

The Ovarian Hormone.

The problem of the prevention and interruption of pregnancy by physiological means is attracting considerable attention at the present time, and several investigators are reporting results of importance. Some, however, would seem to be unaware of similar work already carried out. It was in 1925 that I first reported that pregnancy could be interrupted by the injection of the so-called œstrous hormone (*Biol. Ges. zu Wien*, Dec. 7, 1925). At that time I was using extracts prepared by Heinlein and Hohlweg, and others prepared and used by Steinach, Heinlein, and Wiesner in earlier investigations. Fellner (*Wr. klin. Wschrift*, 1926) raised the objection that the effect of these extracts might be due to the action of non-specific substances included therein. By using highly purified extracts, prepared for the most part by Dohrn and his co-workers, I was able to remove this objection, since abortion was produced in rats, guinea-pigs, and mice, even when small doses, 0·0002 mgm., were administered. Injections of many times this quantity of other substances (lipoids) produced no effect. Since more units (mouse-units) are required when moderately pure extracts are used, it is reasonable to assume that in these cases the effect was due to the specific action of the hormone.

The working hypothesis which has guided me in this work is that there exists a certain correspondence between the phases of the sexual cycle and the level of the œstrous hormone. It will be recalled that the genitalia of those animals which have a diphasic sexual cycle (rats, mice, guinea-pigs, cattle, sheep, dogs, etc.) exhibit two successive states. The uterus and other organs first pass through the sexual (œstrous) phase and then through the reproductive phase (pregnancy or pseudo-pregnancy). As both phases are occasioned by the endocrine functioning of the ovary (as is definitely proven in the case of pseudo-pregnancy), the question arises as to what the mechanism is that is responsible for the change from the first to the second phase. Two possibilities present themselves. There might be a change either in the quality of the ovarian hormone or else in the manner in which the uterus and other genitalia react to the follicular hormone.

During preliminary experiments, it was found to be impossible to provoke the typical phenomena of the first or sexual phase by injection of œstrous hormone during pregnancy. This result seemed to indicate that the change from first to second phase was due to an altered power of reaction on the part of the genitalia to the follicular hormone. But in the spayed female it was found to be impossible to provoke the exhibition of the phenomena of the reproductive phase even when using large quantities of œstrous hormone and under conditions similar to those that operate in the case of the normal animal (coitus, etc.). It was assumed, therefore, that this œstrous hormone is but one of the factors constituting the ovarian hormone—the α-factor—and that for the production of the second phase the action of another factor, the β-factor, is required. The α-factor certainly plays a certain rôle in the production of the second phase, since it can be demonstrated that the genitalia react to it in a specific fashion during the second phase. It would seem to follow from this that the greatest production of œstrous hormone occurs during that stage when no œstrus appears (*i.e.* pregnancy), and that with the progress of pregnancy the amount increases. The indications are that there appears to be both a change in the production of hormone with the incoming of the β-factor, and also in the manner in which the genitalia react to the α-factor.

Since any stage of pregnancy (embryonic development) depends on a certain anatomical and functional state of the uterus, and since this state of the uterus depends on the hormonic level, any artificial raising of the hormonic level will produce a state within the uterus which is unfitted to the stage of development reached by the fœtus. For this reason abortion follows injection of one of the factors of the ovarian hormone.

By the same means it is possible to inhibit pregnancy. The first phase can be prolonged by injection of the α-factor, with the result that the uterus does not pass into the second phase, and so no preparation is made for the arrival of the ovum.

These observations apply only to the case of animals with a diphasic cycle. They do not hold in the case of man, monkey, and rabbit, forms with a monophasic cycle, for no separate first phase exists in these, the whole cycle consisting of a series of changes comparable only with pseudo-pregnancy. Menstruation is nothing else than the termination of pseudo-pregnancy, and has nothing whatsoever to do with œstrus and œstrous bleeding. The complete monophasic cycle is to be compared with the second phase of the diphasic cycle.

In all monophasic animals, however, the α-factor plays an important rôle. Every stage of pseudo-pregnancy (pre-menstruum) and pregnancy corresponds to a certain level of the α-factor (Zondek, Smith, etc.). By raising the level of the α-factor artificially, there is produced a stage more advanced than that appropriate to the stage of development of the embryo.

Prices of Periodical Scientific Publications.

The high prices that are being charged by certain Continental publishers for scientific journals issued by them brings up the very serious question of the steps which must be taken by learned societies, institutions, and individuals against these extraordinary prices. The journals are wanted for reference by research workers all over the world, but their prohibitive prices are in many cases making it impossible for most institutions to continue subscribing to them, while for a great majority of individual workers to purchase single volumes at £7 7*s.* to £8 8*s.* is absolutely out of the question. A great amount of material is apparently available for publication, as three to four volumes of various journals are issued every year. The prices for subscription of different volumes are not on a regular rate, but an arbitrary price is fixed for each part of the different volumes. This results in the subscription for various journals amounting to as much as £20 a year.

I give below a few cases with the actual printed prices of the volumes for the year 1927. *Ergebnisse der Anatomie und Entwicklungsgeschichte*, which up to vol. 22 for 1914 (issued in 1916) was published by J. F. Bergmann, Wiesbaden, and was taken over by the combine of publishing firms of J. F. Bergmann, Munich, and Julius Springer, Berlin. It now forms the third part of *Zeitschrift fur die gesamte Anatomie*. The last volume, 27, issued in November 1927, consists of 1104 pages with 271 text-figures; there are no plates. The price of this volume is 168 Reichsmarks, or roughly £8 8*s.* The price of three volumes of *Zeitschrift fur Anatomie und Entwicklungsgeschichte*, issued during 1927 and forming part 1 of the above-mentioned series, comes to Reichsmarks 405, or £20 5*s.*; the price per volume would work out roughly at £7. The volumes of *Wilhelm Rouxs Archiv fur Entwicklungsmechanik*, issued during 1927, cost Reichsmarks 380, or £19, and the price of a single volume varies between £5 5*s.* and £7. The two volumes of *Zeitschrift fur Zellforschung und mikroskopische Anatomie*, issued during 1927, cost Reichsmarks 240, or £12.

The above publications are all issued either by Bergmann and Springer or by Springer alone. The case of *Archiv fur Naturgeschichte*, issued by the Nicolaische Verlag, Berlin, is no better. Of the two volumes of this serial, more than a dozen parts are issued every year at an average price of Reichsmarks 30 to 36, and the average cost of the serial works out at about £20 a year. For comparison one might refer to journals like *Zoologische Jahrbucher* or *Archiv fur Protistenkunde*, prices for the different volumes of which vary between 60 and 80 marks, or £3 to £4. The size of text and number of illustrations, both in the form of text figures and plates of these serials, would compare very favourably with any of the journals mentioned above.

The cost of printing has undoubtedly gone up since the War, but are these exorbitant prices justified? And can various institutes and societies, with their moderate grants or income, continue subscribing to these journals? I am afraid it is practically impossible for many institutions, like the Zoological Survey of India, which has complete sets of all the journals mentioned above, to continue subscribing to them much longer, unless the prices are materially reduced or their library grants are increased. In the interest of workers, could not various bodies like the Royal Society of London, the Zoological Society of London, and other similar institutions, take up the matter and consider what steps can possibly be taken to deal with the difficult situation?

The Oldoway Skull.

I have recently returned from Germany, where by the kindness of Dr Hans Reck I was enabled to examine the Oldoway skull and skeleton found by him in 1913 in what was then German East Africa—now Tanganyika Territory—and I have also fully discussed the geological and palæontological evidence as to its age with Dr. Reck himself.

The object of my visit was to see how nearly the Oldoway skull compared with, or how it differed from, the fossil human skulls which I brought back from Elmenteita, Kenya Colony (see Nature, July 16, 1927, p. 85).

With Dr. Reck's permission I am able to make the following statement about the Oldoway skull, though of course I may not give any measurements, as Prof. Mollison of Munich is now preparing a detailed report of the skull and skeleton for publication.

All the following statements are the result of my own personal examination of the skull and of my discussion with Dr. Reck.

(1) The Oldoway skeleton lay in a crouched position on its right side beneath undisturbed alluvial deposits belonging to the last pluvial period. The crouched position of the body certainly suggests burial, but if it was a burial it was quite certainly not from the present land surface, but from an earlier surface, for at least 3 metres of undisturbed alluvial strata lay above it. Dr. Reck inclines to the idea that the body became embedded when the deposits were forming under marshy conditions, for no trace of even a shallow grave was found.

(2) The undisturbed deposits lying above and below the skeleton were very rich indeed in mammalian remains. These, while including a number of forms such as eland and oryx, which are indistinguishable from living species, nevertheless consist—so Dr. Reck tells me—to more than 50 per cent. of extinct fauna. The latter includes a number of hitherto unknown genera and species of antelope; a new sheep; numerous remains of an elephant closely allied to *Elephas antiquus* which has been named *Elephas antiquus Recki*; extinct hippopotamus and rhinoceros; and a three-toed horse closely allied to hipparion. Despite the last-mentioned animal—which he considers as a survival from Pliocene or earlier times—Reck regards the deposit as belonging to the end of the Pleistocene.

(3) The human skull from Oldoway very closely resembles some of my fossil skulls from Elmenteita, which, I suggest, also belong at latest to the beginning

of the last pluvial period. It is most decidedly non-negroid, having a long leptorrhine nose, a very long upper-face and a premaxilla of unusual length, with a correspondingly deep palate. All of these characters are found in my Elmenteita skulls.

(4) I could see no sign at all of the suggested artificial chipping of the teeth which is one of the reasons why the Oldoway skull has been considered by many as a recent Bantu burial in fossiliferous deposits. I was only able to examine the upper jaw, as Dr Mollison was away from Munich at the time of my visit and the lower jaw was locked up in his room. Recent photographs of the mandible, however, betray no evidence of chipping at all.

It is thus clear that Dr. Reck's find is in close agreement with the Elmenteita evidence, and it indeed looks as though an early form of *Homo sapiens* lived in East Africa before the last pluvial period, accompanied by numerous animals now extinct.

A full report dealing with the human remains and the associated industries found during last year's expedition is in course of preparation.

Feb. 28.

Strong Electrolytes.

IN the original form of the Debye-Hückel theory, the solvent enters only as the medium, having a certain dielectric constant, through which the electric forces between the ions act. In his extension of the theory to concentrated solutions (*Physikal. Zeitschrift*, **26**, 93; 1925) Hückel discussed at some length the effect of the electric field of the ions on the solvent molecules, and pointed out that polarisable molecules tend to congregate round an ion where the electric field strength is greatest, thereby tending to displace other ions from its vicinity. Hückel considered that the effect of this behaviour was obtained by introducing into the equations "the phenomenological law that the dielectric constant of the solution diminishes with increasing electrolyte concentration." While his equations were capable of reproducing the activity coefficients of salts, even in concentrated solutions, using constants obtained from the data themselves, it is doubtful whether these constants have the postulated relation with the dielectric constant lowerings actually produced by electrolytes (*cf.* Harned, *J. Amer. Chem. Soc.*, **48**, 326; 1926).

A more direct calculation might be made by making use of the result (*see* G. H. Livens, "Theory of Electricity," 1926, p. 82) that the work done by an element of dielectric of volume δv, in going from a position where the electric field is zero to one in which the field strength is E and the polarisation P, is

$$\delta v\int P\,dE = \frac{\epsilon - 1}{2}E^2 \cdot \delta v,$$

assuming proportionality between P and E.

When an ion is brought up from a great distance to a point in the vicinity of a given ion it displaces a quantity of solvent molecules having the same volume. Thus the total work done by an ion of volume Δv in reaching a point where the potential is ψ is

$$e_1\psi + \frac{\epsilon - 1}{2} \cdot E^2 \cdot \Delta v,$$

and the Debye equation

$$n_1 = n_{10}e^{-\frac{e_1\psi}{kT}}$$

is replaced by

$$n_1 = n_{10}e^{-\left(\frac{e_1\psi}{kT} + \frac{\epsilon - 1}{2}\ \Delta v \cdot \frac{E^2}{kT}\right)}.$$

By the use of Poisson's equation we get

$$\nabla^2\psi = -4\pi\Sigma e_1 n_{10}e^{-\left(\frac{e_1\psi}{kT} + \frac{\epsilon - 1}{2} \cdot \Delta v\ \frac{E^2}{kT}\right)},$$

or to a first approximation

$$\nabla^2\psi = \kappa^2\psi \cdot e^{-\lambda(\nabla\psi)^2},$$

where κ has the usual meaning and $\lambda = \frac{\epsilon - 1}{2kT} \cdot \Delta v$.

I have been unable to obtain a solution to this equation, and I should be grateful for any suggestion as to how a solution (approximate or otherwise) might be obtained.

The Atomic Spectral Lines Associated with the Band Fluorescence of Alkali Metals.

THE band spectrum of sodium in the visible region consists of two systems, one in the red on the longer wave-length side of the yellow D lines, and another stronger one in the green on the shorter wave-length side of these lines (R. W. Wood, *Phil. Mag.*, **18**, p. 530; 1909). Potassium possesses two similar band systems (J. C. McLennan and Ainslie, *Proc. Roy. Soc.*, **103**, p. 304; 1923). It is now known that the bands on the red side belong to a triplet system, $^3P \rightarrow {}^1S$, and those on the blue side to a singlet system, $^1P \rightarrow {}^1S$. This results from alkali *molecules* having in their normal state two outer electrons like the *atoms* of the alkaline earths.

These band groups can be obtained on the spectrograms of the light emitted by metal vapours that have been rendered fluorescent. By illuminating sodium vapour with the blue-green radiation of sunlight, for example, the light giving the bands on the short wave-length side of the D lines is emitted throughout the vapour. When spectrograms are taken of this emitted fluorescent light, it is always found that they include the yellow *atomic* lines of sodium in addition to the *molecular* fluorescence bands. This feature characterises the fluorescence spectrum of sodium even when the incident light stimulating the fluorescence is wholly free of the wave-lengths 589 and 330 $\mu\mu$, and therefore could not *directly excite the atomic lines*.

A still more remarkable feature of these fluorescence spectrograms is that the D lines appearing on them are very broad even at low temperatures (200°-300°) and at moderate pressures ($p < 1$ mm. at 300° C.).

The information recently acquired regarding the dissociation of homœopolar molecules through the investigation of band spectra enables us to account satisfactorily for these features. The emission of the atomic resonance lines is the result of the dissociation of the excited molecules. Molecular dissociation can take place when the energy associated with a quantum of the absorbed light is greater than the energy, V_r, corresponding to the atomic resonance potential plus the energy, D_r, representing the heat of dissociation.

In the case of sodium, D_r amounts to the equivalent of 1·3 volts, and in the case of potassium to 0·6 volts. If U be the energy equivalent of the quantum of the light absorbed, the excess energy represented by $U - (V_r + D_r)$ would appear in molecular dissociation as kinetic energy of the atomic products of such dissociation, and this kinetic energy in turn would account for the abnormal width of the D lines.

The considerations presented above also afford an explanation of why the absorption of red and green spark-line radiation does not bring about the emission of the yellow D lines from sodium vapour. Work is in progress to develop the ideas expressed above.

The Sligo Artefacts.

A LETTER in NATURE of Jan. 28 definitely establishes the human origin of the Sligo flakes, but the last sentence of the letter seems to suggest some mystery concerning their cultural age. In view of this it may not be superfluous to refer to the accompanying photograph (Fig. 1) which Mr. A. W. Stelfox has kindly lent us. The photograph (Fig. 1) was taken by Mr. R. W. Welch and shows a primitive limestone anchor similar to many that are still manufactured and used by the fishermen on the west coast of Galway. These anchors are made near the coast, and the resulting flakes are left lying about along with larger discarded stones, all showing traces of their undoubted 'humanity.' Although no such anchors are now made at Rosses Point, it is highly probable, if not certain, that such stone anchors were made there, and also at many other parts of the Irish coasts one or two hundred years ago. In all probability the present beach on which the Sligo specimens were found was not in existence even a thousand years ago, so the possibility of the Sligo flakes being debris from primitive stone anchors should be taken into consideration when attempting to fix their cultural age.

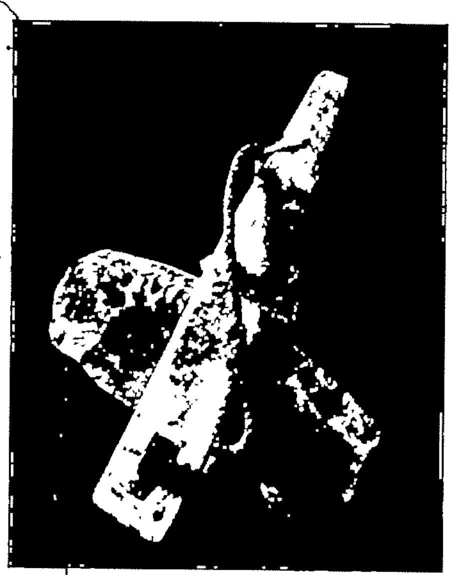

FIG. 1.—Primitive anchor, a heavy stone in wooden clamp, still used by Aran Islanders, west coast of Galway.

These facts are no doubt known to the five signatories of the letter referred to, yet we think it worth while to place on record any evidence which might assist in the elucidation of the cultural age of the artefacts in question.

Factors which determine the Occurrence of the Green Ray.

THE recent discussion of the green ray which has been appearing in NATURE prompts me to put on record a new theory of the phenomenon which occurred to me several years ago, but which I have refrained from publishing in the hope of securing proof. First let me say most emphatically that the phenomenon is real and not an illusion or after-image. No person trained in the observation of optical effects, both real and subjective, who has seen the phenomenon at its best, will have any doubt about its reality. There is also no question in my mind but that the usual explanation (atmospheric dispersion) is quite correct. The main question to answer is, Why is it seen so seldom, even under conditions which appear to be the most favourable?

I have crossed the ocean some thirty times and have looked for the 'ray' at every favourable opportunity, by which I mean clear sky, no haze or clouds on the horizon at sunset, and a calm sea, and yet I have observed it on only three or four occasions, and only once when it was really striking. This occasion was on an eastward trip of the *Homeric*, sailing from New York on June 6, 1925. The colour of the vanishing edge of the sun at sunset was a vivid emerald green, about the colour of a railroad signal light. On other occasions on which I have observed evidence of the phenomenon, the colour change was from red or orange to lemon yellow.

It seems possible that the determining factor is the relative temperature of the air and the ocean. Warm water and cool air would flatten the trajectory of the light rays, and cause the sun to set abnormally early. This is the type of refraction in cases of desert mirage, in which case the curvature of the rays is reversed. With cold water and warm air, on the contrary, the normal gradient of refractive index would be increased, the curvature of the rays augmented, and sunset would be delayed, giving a greater opportunity for atmospheric dispersion to come into play.

Through the courtesy of Capt. Parker, of the *Homeric*, I have been furnished with data regarding the air and water temperatures on this trip. On the day on which we observed the ray, the temperatures of air and water were practically the same at sunset. On the other three favourable evenings, on which we failed to see any trace of the phenomenon, the ocean was from twelve to fourteen degrees warmer than the air at sunset. I hope that this note may prompt future observers of the green ray to secure data on the air and water temperature, both for occasions on which it is not seen, as well as those on which it is well marked.

R. W. WOOD.

Johns Hopkins University,

A New Type of Secondary Radiation.

IF we assume that the X-ray scattering of the 'unmodified' type observed by Prof. Compton corresponds to the normal or average state of the atoms and molecules, while the 'modified' scattering of altered wave-length corresponds to their fluctuations from that state, it would follow that we should expect also in the case of ordinary light two types of scattering, one determined by the normal optical properties of the atoms or molecules, and another representing the effect of their fluctuations from their normal state. It accordingly becomes necessary to test whether this is actually the case. The experiments we have made have confirmed this anticipation, and shown that in every case in which light is scattered by the molecules in dust-free liquids or gases, the diffuse radiation of the ordinary kind, having the same wave-length as the incident beam, is accompanied by a modified scattered radiation of degraded frequency.

The new type of light scattering discovered by us naturally requires very powerful illumination for its observation. In our experiments, a beam of sunlight was converged successively by a telescope objective of 18 cm. aperture and 230 cm. focal length, and by a second lens of 5 cm. focal length. At the focus of the second lens was placed the scattering material, which is either a liquid (carefully purified by repeated distillation *in vacuo*) or its dust-free vapour. To detect the presence of a modified scattered radiation, the method of complementary light-filters was used. A blue-violet filter, when coupled with a yellow-green filter and placed in the incident light, completely extinguished the track of the light through the liquid or vapour. The reappearance of the track when the yellow filter is transferred to a place between it and the observer's eye is proof of the existence of a modified scattered radiation. Spectroscopic confirmation is also available.

Some sixty different common liquids have been examined in this way, and every one of them showed the effect in greater or less degree. That the effect is a true scattering and not a fluorescence is indicated in the first place by its feebleness in comparison with the ordinary scattering, and secondly by its polarisation, which is in many cases quite strong and comparable with the polarisation of the ordinary scattering. The investigation is naturally much more difficult in the case of gases and vapours, owing to the excessive feebleness of the effect. Nevertheless, when the vapour is of sufficient density, for example with ether or amylene, the modified scattering is readily demonstrable.

Land-locked Salmon.

The term 'land-locked' is generally used for fresh-water colonies of salmon, such as that from the River Otra described in Nature of Mar. 17, and from Lakes Wenern and Ladoga, and even for the Canadian Ouananiche. The word is, in my opinion, misleading, indicating that the colony is cut off from the sea, which is not always true, and that it owes its formation to this circumstance.

The fact that Lake Wenern has a stock of salmon indicates that it was formerly accessible from the sea; when the falls first became impassable to ascending fish they could scarcely have prevented fish from descending had they wished, so that none would be left. It seems clear that in the days when the lake was accessible from the sea, and salmon went through it to spawn in its tributaries, some of the smolts that descended into the lake found it to be a sufficiently good substitute for the sea to stay there, and so founded a non-migratory race, which became isolated later. Similarly with the River Otra; some of the smolts reaching the Bygglandsfiord were tempted to stay and feed on the abundant pelagic crustacea, and founded a dwarfed race of lake-salmon, that was isolated when the falls became impassable.

The trout forms fresh-water colonies in every river and lake that it enters, and for this species the term 'land-locked' is never used. On this side of the Atlantic the salmon generally leaves such colonisation to the trout, and itself forms fresh-water colonies only in exceptional circumstances, either in very large lakes with abundance of fishes, or in rivers or lakes with such quantities of parr-food that it is tempted to prolong the parr life. In America, when there are no trout, the salmon form fresh-water colonies more readily.

Anomalous Groups in the Periodic System of Elements.

In a paper which will shortly appear in the *Rend. Accad. Lincei*, I have calculated the distribution of the electrons in a heavy atom. The electrons were considered as forming an atmosphere of *completely degenerated* gas held in proximity to the nucleus by the attraction of the nuclear charge screened by the electrons. Formulæ were given for the density of the electrons and the potential as functions of the distance r from the nucleus.

In continuation of the previous work, I have applied the same method to the study of the formation of anomalous groups in the periodic system of elements. From the density of the electrons and their velocity distribution, one can easily calculate how many electrons have a given angular momentum in their motion about the nucleus, that is, how many electrons have a given azimuthal quantum number k.

It is known, for example, that the formation of the group of the rare earths corresponds to the bounding of electrons in 4_4 orbits, that is, to the presence in the atom of electrons with $k=4$. Now it follows from the theory that electrons with $k=4$ exist in the normal state only for atoms with atomic number $z \geq 55$. This agrees well with the empirical result that the group of the rare earths begins at $z=58$ (cerium).

Similarly, the bounding of 3_3 electrons with $k=3$ corresponds to the anomaly of the first great period beginning at $z=21$ (scandium); according to the theory, electrons with $k=3$ should appear in the atom just at $z=21$.

Further details will be published later.

Activation of Ergosterol at −180° C.

With reference to the letter in Nature of Mar. 24, p. 452, from Dr. Bills and Mr. Brickwedde, on the activation of cholesterol at liquid oxygen temperature, we may mention that we are now studying the production of vitamin D from ergosterol by ultra-violet radiation at various temperatures, and have obtained intensely active products at −180° C. from weak alcoholic solutions immersed in liquid oxygen, as well as at higher temperatures up to +78° C. Details will be published shortly. Our results therefore are similar to those of Bills and Brickwedde, and are made with the pure provitamin instead of with 'cholesterol.'

Recent Progress in Theoretical Physics.

By H. F. BIGGS.

WHEN an army is making a rapid advance over fresh ground it is not the time to make an elaborate survey of the territory conquered, but on the other hand sketch maps, however provisional and imperfect, of the main lines of advance and the chief points of attack, are all the more useful to the soldier in the field and interesting to the newspaper reader at home. What follows is an attempt to draw such a sketch map for some important recent work in physics.

The most remarkable thing about present-day physical theories is the strange dual nature all the components of matter and energy seem to exhibit. Thus no sooner does Bose (*Zts. f. Phys.*, **26**, 178; 1924) show that Planck's law of temperature radiation can be derived by treating quanta $h\nu$ as if they were particles with momentum $h\nu/c$, than Einstein (*Berl. Ber.*, 261; 1924) follows suit by applying Bose's method to the molecules of a material gas, supporting his procedure by treating his molecules as equivalent to wave-trains after the fashion of L. de Broglie. A new statistical principle is introduced by Bose, but it will be easier to explain this after we have considered the rival principle commonly called the Fermi-Dirac statistics. This latter principle may be stated in a few words as the extension to quantised translational motion of Pauli's prohibition, by which no two electrons in an atom can have exactly the same set of quantum numbers.

But how are translational motions of particles to be quantised? This question can be most easily answered by considering the de Broglie waves of our particles (L. de Broglie, *Ann. de Phys.*, **3**, 22; 1925; or Biggs, "Wave Mechanics," p. 22). A moving particle is equivalent to a train of waves (ψ-waves) the wave-number of which is p/h, where p is the momentum of the particle and h is Planck's constant. The components, too, of the momentum are proportional to the wave-numbers along the co-ordinate axes, that is, to the number of waves per centimetre cut by the axes respectively. Thus we write

$$N_x = p_x/h,\ N_y = p_y/h,\ N_z = p_z/h \qquad (1)$$

The elastic rebound of a molecule from a boundary wall is now equivalent to the reflection of ψ-waves from the wall, since the laws for angles are the same, and thus an ideal gas in an enclosure with perfectly elastic walls is replaced by a field of ψ-waves in an enclosure the walls of which are perfectly reflecting for these waves. This only means that if there is to be no progressive motion of particles or radiation through any surface drawn in a gas, the wave-system must be a stationary system such as would be formed by trains of waves reflected to and fro at the surface. The problem of velocity distribution in a gas is then closely related to the Rayleigh-Jeans problem of finding the number of degrees of freedom or modes of oscillation in a given volume of a continuous medium. (See Jeans, "Dynamical Theory of Gases," chap. xvi.; 1921.)

A less mathematical argument than the usual one may be used, and is more appropriate to the case in hand. Let the oblique lines in the diagram (Fig. 1) be the traces of wave-fronts in the original train and in a train formed by reflection at some vertical wall, the full lines representing crests and the dotted lines troughs. Then the reflecting walls must be either in positions such as w, w, if at nodes of the standing waves, or W, W, if at antinodes. In either case, a line drawn normal to the planes must cut a whole number of *half*-waves. Thus in a rectangular box, with edges a, b, c, cm. parallel to the axes, $2aN_x$, $2bN_y$, $2cN_z$ must be whole numbers,

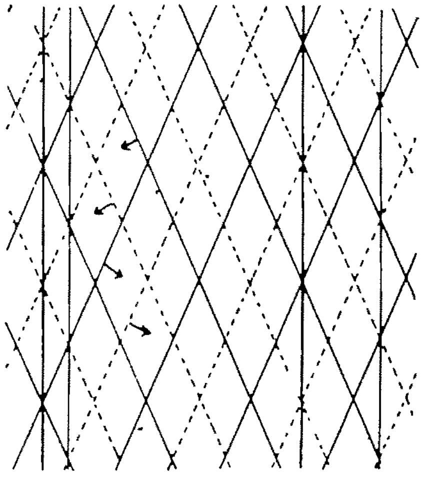

FIG. 1.

where N_x, N_y, N_z are positive quantities giving the wave-numbers without regard to sign. If we then represent the possible wave-trains each by a point the rectangular co-ordinates of which are $2aN_x$, $2bN_y$, $2cN_z$, we obtain a cubic space-lattice in the positive octant of space alone the constant of which is one unit; if, however, we take N_x, N_y, N_z themselves as co-ordinates, the unit cell of our representative space-lattice will be a rectangular parallelepiped of dimensions $1/2a$, $1/2b$, $1/2c$, and finally by (1), the possible *momenta* of particles in the box will be represented as to the absolute magnitude of the components by the points of a space-lattice in the positive octant the unit cell of which measures $h/2a$ by $h/2b$ by $h/2c$.

It will be noticed that we have thus quantised the linear momentum of a particle in our box in almost the same way as de Broglie quantised the angular momentum of an electron describing a circular orbit. In our case, it is the number of half-waves along the length, breadth, or depth of the box that must be a whole number; in de Broglie's case, it is the number of waves counted 'round the orbit.' In both cases quantisation expresses the existence of a steady state, or, from another point of view, the existence of a single-valued function ψ.

We can now see clearly how we are going to get the theory into relation with classical and 'classical-quantum' statistical dynamics. But first we must take a rather different space-lattice for our possible momentum-points, not occupying only the positive octant of space but also extending symmetrically on all sides of the origin. We evidently get the same number of points up to a given maximum value P of the momentum if we take, instead of a spherical octant of radius P, a whole sphere of radius P, provided we multiply the volume of our unit momentum cell by 8, making its edges now h/a, h/b, h/c, instead of half these lengths. Then the unit cell in the momentum-space for a particle in a box abc will have the volume h^3/abc, and the unit cell of the 6-dimensional phase-space with co-ordinates x, y, z, p_x, p_y, p_z, will have the volume h^3. It will not be necessary, however, for our purposes to fuse the real space and the momentum space into a 6-dimensional continuum, but it will be more convenient to keep the conceptions of the two spaces distinct.

Now so far we have postulated no statistical principle whatever, but have left it quite indeterminate *how many particles* there may be to each point of our momentum space-lattice. Leaving until later the Bose-Einstein principle and the classical principle of assigning these numbers, we will follow out some consequences of the answer that arises most naturally from our train of reasoning, namely, that *no two particles can have the same lattice point*, that is, no two particles can have the same momentum in the same direction—and in particular, even at the zero of temperature when the system has radiated all the energy it can radiate, only one particle can have zero momentum or zero energy. This is the Fermi-Dirac principle (Fermi, *Rend. Accad. Lincei*, **3**, 145; 1926; Dirac, *Proc. Roy Soc.*, A, **112**, 661; 1926). It must hold for the same reason that the similar Pauli principle holds for the electrons in an atom, though what this reason may be is a puzzle. One may perhaps hazard the guess that if two molecules or two electrons had the same wave-trains, or oscillations the same in all but phase, they would no longer be the distinct entities of our experience, the discreteness of motions being thus very intimately bound up with the atomic nature of matter itself.

This reasoning of course is quite right only for *structureless* particles which alone can be fully represented by the oscillation of a scalar such as ψ; it should hold, therefore, for a monatomic gas for all phenomena that are not influenced by atomic structure, but for the spinning electron there may be *two* electrons instead of one per lattice point, as in the Stoner atomic scheme. The statistical principle is just the same, but the representation loses a little in *Anschaulichkeit*.

For a true particle we may now state the principle thus: *The product of the real space available per particle and the least momentum space which must be assigned to each particle is h^3.* The first consequence of this is that at the zero of temperature the actual momenta of the particles will not be zero, but their representative points will be close-packed, occupying all those points of our lattice which lie closest to the origin or zero of momentum with one cell of volume h^3/V per particle. Thus, if we have N particles confined within V cubic centimetres, their momentum space will have the volume Nh^3/V; and since the shape of this volume will presumably be spherical (for N large), we can easily calculate the energy. For if P be the radius of this sphere, we have, to find P

$$(4\pi/3)P^3 = Nh^3/V,$$

and the kinetic energy of a particle with momentum p is $p^2/2m$, so that dividing the total energy

$$\frac{V}{h^3}\int_0^P 4\pi p^2 dp \frac{p^2}{2m}$$

by the number of particles

$$\frac{V}{h^3}\int_0^P 4\pi p^2 dp,$$ we get for the mean energy

$$\frac{1}{2m}\cdot\frac{3}{5}P^2 \text{ or } \frac{3h^2}{10m}\left(\frac{3N}{4\pi V}\right)^{\frac{2}{3}}.$$

A striking application of this result was made by R. H. Fowler (*Mon. Not. Roy. Astr. Soc.*, **87**, 114; 1926; see also Eddington: "Stars and Atoms," Oxford, 1927, Appendix) to the dense matter of the companion of Sirius, showing that even when such matter has radiated all the energy it can, and has cooled down to the absolute zero, the 'free' electrons, of which (as regards number and energy) it is chiefly composed, have a mean energy corresponding to equipartition energies at something like 10^8 degrees.

Some of the mysteries of matter in its more familiar forms can also be illuminated by this principle in the most hopeful way. Thus Pauli (*Zts. f. Phys*, **41**, 81; 1926) shows that the small paramagnetism of metals can be accounted for by treating the free electrons as magnetic molecules of a gas near the absolute zero. For corresponding temperatures are inversely as the masses of the particles concerned, so that to the helium molecule at 5° abs corresponds electron gas at about 36,000°. If then we start filling up the lattice points with electrons, two go to each point, and these have opposite orientations, so that the resultant magnetic moment must be zero, to the first approximation. Pauli pursues the analysis further and derives Curie's law (kT = const.) for the susceptibility and finds absolute values which promise to agree well with observation when we know better the intrinsic diamagnetism to be assigned to the various atoms.

More recently, Sommerfeld (*Naturwiss.*, **15**, 825; 1927) has attacked other hitherto baffling problems of electronic phenomena in metals with very promising results, building on the Drude treatment by mean free paths, but using the Fermi-Dirac statistics instead of the Maxwell statistics of Lorentz. The great stumbling-block of the negligible contribution of the electrons to the specific heat is surmounted at the first stride, since the degradation or high quantisation of the electronic motions gives a value for the specific heat which vanishes at 0° abs. (in accordance with Nernst's theorem) and at ordinary temperatures is only of the order $R/100$, which is quite compatible with observation. The formulæ for the electric and the thermal conductivity depend on the mean free path and cannot yet be satisfactorily checked, but in their ratio, the Wiedemann-Franz coefficient, this unknown divides out, and the result, $\frac{\pi^2}{3}\left(\frac{k}{e}\right)^2 T$, which is the classical formula with the numerical factor $\pi^2/3$ instead of 2, agrees exactly with the observed mean for the various metals. This, however, is not quite so conclusive as it sounds, since even the seven best metals differ among themselves by 8 per cent. Still more convincing are the results for thermoelectric phenomena, which all come out of the right order, where the classical theory is wrong by very large factors on any reasonable assumptions.

It should be noted that Sommerfeld introduces no arbitrary quantities at all, and the only quantity he uses which varies from metal to metal is the number of electrons per cubic centimetre, which he puts equal to the known number of atoms. One interesting result of this procedure is that the contact potentials come out, for the most part, correct in magnitude but wrong in sign. In other words, an electron would escape from its fellow electrons alone at the given density with a *positive* energy equal to the *work that must be done* to get it out from an actual metal containing the same number of positive atoms with the electrons. Thus, with an obvious notation,

$$W_e = W_a - W_e, \text{ or } W_a = 2W_e.$$

This at once suggests an analogy with the familiar theorem that the potential energy is minus twice the kinetic energy for particles obeying the inverse square law (Sommerfeld, "Atombau," Appendix). For the interactions (if this word can be used at all) of the electrons which cause them to obey this new statistics seem to have nothing to do with their ordinary electrostatic repulsions, so that W_e calculated by the statistics will presumably correspond to kinetic energy, and W_a to potential energy.

There can be no doubt that this paper of Sommerfeld's forms the first[1] step in the true theory of metallic conduction, and that the preponderating factor in these phenomena depends on this statistical behaviour of the electrons without regard even to the structure of the metallic crystals. The next step, as Sommerfeld remarks, will be to improve on the assumption of a constant mean free path and to discover how this quantity depends on the velocity of the electrons and on the temperature.

Let us now return to the question of the different possible statistical principles and trace out the connexion between them. All statistical problems can be regarded as depending on the number of ways a number of objects can be put into a number of boxes with different labels under various rules. For gases the objects have until now been molecules and the boxes cells of phase space. Classically, the cells are taken equal in size, the intrinsic probability of a molecule being in one of these cells is the same for any cell, and finally the cells are made infinitely small. In the classical quantum theory of Nernst and many other workers, the only difference is that the cells are not made infinitely small but have the finite size h^3; they still are regions of equal size and of equal probability. But for both the new statistical principles the point of view is entirely different; we consider, not into which cell we put a particle, but how many particles a cell contains. On the Fermi principle, each cell may contain one particle, but not more, and it is further assumed that to contain one particle and to contain no particle are equally probable states for a given cell. In terms of objects and boxes, it is the cells that are now the objects, and there are only two boxes, which have equal chances of receiving a given object (*i.e.* cell), one labelled 'no particle' and the other 'one particle.'

As we have seen, there seems to be some sort of intelligible reason for this principle, but the Bose-Einstein principle is thoroughly baffling[2] as to reasons, though easy enough to express. It runs: *It is equally probable that a cell will contain any number of particles.* Or, with the cells still as objects, the boxes of equal probability are labelled 0 *particle*, 1 *particle*, 2 *particles*, and so on. Jordan (*Naturwiss.*, 15, 636; 1927)[3] illustrates the application of the three principles to the simple case of two particles and two cells by this diagram (Fig. 2).

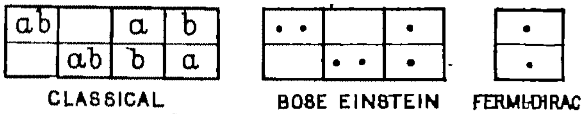

FIG. 2.

In the classical quantum theory we can suppose the particles named *a* and *b*. Then the arrangements with both in the first cell and with both in the second cell will have one complexion each and will be equally probable, while the arrangement with one in each cell will have two complexions and will therefore be twice as probable. On the Bose principle, on the contrary, the particles have lost all individual distinction and can be represented by mere dots. The arrangement with one particle in each cell has then only one complexion and has the same probability as either of the arrangements with both particles in one cell. On the Fermi principle the only possible arrangement is with one particle in each cell. Then, on any theory, once the intrinsic probability is settled, the steady state of maximum probability can be found by the familiar methods.

---

[1] This is not quite fair to Lindemann, who some time ago suggested that the electrons form a nearly rigid space-lattice among themselves (F. A. Lindemann, *Phil. Mag.*, 29, 127; 1915). So they do, but it is in the momentum space, not the real space.

[2] See, however, a short and most suggestive paper by Brillouin (*Comptes rendus*, 184, 589; 1927), in which he shows that in the Bose scheme the probability of a quantum getting into a cell is *greater* the more quanta there are already in that cell. It is like the game of chain-tig, in which the more boys there are in the chain the greater is the chance of their adding to their number. This is only a fanciful way of putting the fact that the greater the radiation density corresponding to a certain energy-jump, the greater is the probability of the radiation provoking another such jump, as in Einstein's proof of Planck's law in 1917

[3] In this and a paper in the previous number Jordan gives a most comprehensive review of the progress of the new theories in the last two years, with a full bibliography.

We have seen that the Fermi principle can be used for electrons not attached to particular atoms, and Fermi in his original paper (*l.c.*) showed that it gave what is probably the true equation of state for a monatomic gas at low temperatures, while Einstein's application of Bose's statistics to gases led to curious results not confirmed by experiment. It seems, therefore, that Bose's original application of his statistical principle to quanta is the only permissible one. Why quanta indistinguishable in every respect should be capable of coexisting when electrons are not is by no means obvious. Quanta seem to be much more indifferent to each other's existence than material particles, which perhaps has something to do with their own indifference to life, or rather their readiness to undergo metempsychosis.

Obituary.

DR. F. RASCHIG.

DR. FRIEDRICH RASCHIG, whose numerous scientific investigations in the domain of chemical technology covered a remarkably wide range and whose interests were not restricted to purely technical problems but were devoted to public welfare, passed away on Feb. 4 at the comparatively early age of sixty-four years.

We are indebted to the *Chemiker-Zeitung* for some points in Dr. Raschig's life. Born on June 8, 1863, at Brandenburg, Raschig's interest in scientific work was awakened while still at the *Realgymnasium*, where he came under the influence of Prof. Müller, director of the *Zeitschrift für physikalischen und chemischen Unterricht*. After studying at the Universities of Berlin and Heidelberg, he became assistant in the University chemical laboratories in Berlin and was afterwards appointed chemist to the Badische Anilin und Soda Fabrik. During this period many publications, dealing chiefly with compounds of nitrogen and sulphur, appeared under his name. In 1891 he started a factory for the manufacture of phenol, but soon afterwards he resumed his studies of the reactions involved in the lead-chamber process for the production of sulphuric acid. The lengthy controversies aroused by this work no doubt did much to stimulate further research in this important field. He also devoted much attention to the reactions of sulphurous anhydride and the sulphites

Dr. Raschig discovered a technical method of preparing hydroxylamine, and his investigation of chloramine led to his well-known process for the manufacture of hydrazine, a compound of considerable interest, which had previously been discovered by Curtius, whose death occurred only a few days after that of Raschig. The latter also elaborated many useful volumetric methods of analysis and was an authority on the manufacture of synthetic phenol and the distillation of coal-tar. Dr. Raschig took an active part in municipal and political life, and in 1924 was elected a member of the Reichstag.

THE issue of the *Physikalische Zeitschrift* for Dec. 15 contains a photograph and a short account of the life and work of the late Prof. A. Gockel, of Freiberge, Switzerland. Gockel was born in November 1860 at Stockach in Baden, where his father was a secretary in the Post Office After attending the Gymnasium at Constance he was in turn a student at the Universities of Freiburg in Baden, Wurtzburg, Carlsruhe, and Heidelberg He graduated in 1885 and held teaching posts in secondary schools for ten years In 1895 he became assistant to Prof. Kowalsky at the University of Freiberge, Switzerland, and in 1901 was appointed lecturer, two years later extra professor, and in 1910 ordinary professor of cosmical physics. In 1921–22 he acted as Rector of the University. He died on Mar. 4 of last year. He married in 1902 the daughter of his colleague Baumhauer, professor of mineralogy. The whole of his scientific publications deal with atmospheric phenomena such as thunderstorms, radiation, and electromagnetic waves, and his work carried him to the shores of the Mediterranean and into the Sahara. His papers are characterised by the carefulness of their deductions.

WE regret to announce the following deaths:

Prof. W. Steadman Aldis, formerly professor of mathematics and principal of the College of Science, Newcastle-on-Tyne, and later of Auckland College, New Zealand, on Mar. 7, aged eighty-nine years.

Mr. W. B. Croft, who taught mathematics at Winchester College for many years, and was widely known for his interest in early work on radiotelegraphy and in optics, on Mar. 23, aged seventy-six years.

Prof. W. W. H. Gee, formerly professor of pure and applied physics at the College of Technology, Manchester, and author of papers and text-books on physics and electro-chemistry, on Mar. 3, aged seventy years

Dr. F. S. Luther, emeritus president and formerly professor of mathematics of Trinity College, Connecticut, on Jan. 4, aged seventy-seven years.

Mr. E. W. Maunder, for many years Superintendent of the Solar Department of the Royal Observatory, Greenwich, on Mar. 21, aged seventy-six years.

Dr. Richard Pribram, emeritus professor of chemistry in the University of Prague, whose work on the optical rotation of organic substances and on the relationship between physical properties and chemical constitution is well known, aged eighty years.

Prof. Herbert M. Richards, professor of botany in Barnard College, Columbia University, and scientific director of the New York Botanical Garden, on Jan. 9, aged fifty-six years.

Mr. A. Shoolbred, author of "The Flora of Chepstow" (1920), a well-known local botanist and horticulturist, on Jan. 25, aged seventy-five years.

Prof. Eilhard Wiedemann, well known for his writings on the history of physics and formerly professor at the University of Erlangen, at the age of seventy-six years.

News and Views.

SUNDAY next, April 1, is the three hundred and fiftieth anniversary of the birth of William Harvey, of imperishable memory, physician and student, prophet of a new world of knowledge through his demonstration of the mechanism of pulsation of the heart in man and animals. Of yeoman parentage, born at Folkestone, Harvey died at Lambeth on June 3, 1657. He was buried at Hempstead, in Essex. Let us not forget, also, that the present year marks the three hundredth anniversary of the issue of Harvey's immortal work, "Exercitatio anatomica de motu cordis et sanguinis in animalibus," published at Frankfort in 1628. It was a small quarto, in Latin, of seventy-two pages, and from the press of William Fitzer, of Frankfort. Previously, Harvey had, in his Lumleian lectures, delivered before the Royal College of Physicians, London, in the spring of 1616, explained his discovery of the circulation of the blood. But his views met with such mixed reception that he was deterred from publishing any treatise on the subject until much later. In this connexion Aubrey tells us that he had heard Harvey say "that he fell mightily in his practice; 'twas believed by the vulgar that he was crack-brained and all the physitians were against him." In the year 1648 another edition in Latin, of 215 pages, appeared at Rotterdam. Afterwards, spreading the wonderful news still farther, came a book of 123 pages in small octavo—"The anatomical exercises of William Harvey concerning the motion of the heart and blood, with the preface of Zachariah Wood, physician of Roterdam. To which is added Dr. James De Back, his discourse of the heart, physician in ordinary to the town of Roterdam. London, 1653"; and the tide of issue rose until all civilised centres and all the teachers knew what had happened. So began, after long delay, man's intimate acquaintance with himself.

THE tercentenary of the birth of Harvey, alumnus of Caius College, Cambridge, and the University of Padua, was celebrated in London fifty years ago by the Royal College of Physicians at a banquet given in their own apartments in Pall Mall. There it was that Huxley, in a remarkable speech, full of tender sympathy and enthusiasm, referred to Harvey's book as "that little essay of fifty pages which no physiologist of the present day can read without wonder and delight." Our readers will find an account of the proceedings in NATURE of June 6, 1878. It may here be mentioned, also, that a statue of the great physician, executed by Mr. Albert Bruce Joy, was unveiled at Folkestone and dedicated to the town by Prof. (afterwards Sir Richard) Owen, on Aug. 6, 1881. There is a famous portrait of Harvey in the possession of the Royal College of Physicians, by Cornelius Jonson van Ceulen; a copy of this hangs in the apartments of the Royal College of Surgeons. The Royal Society also has a portrait, after De Reyn. The National Portrait Gallery has a portrait by an unknown painter.

IN Great Britain and in the United States, numberless friends and admirers of Major-General A. W. Greely, arctic explorer, join in congratulations on the celebration of his eighty-fourth birthday, which occurred on Tuesday last, Mar. 27. Born at Newburyport, Mass., he was educated there at a high school. In early youth Greely enlisted as a volunteer private soldier, serving in the Civil War, 1861–65; afterwards he joined the regular army and was appointed to the signal branch. Following prolonged work of distinction, he succeeded General W. B. Hazen in 1887 as chief signal officer, with the rank of brigadier-general. Under Greely's supervision an enormous amount of telegraphic installation was carried out in Alaska in 1900–1904. General Greely is the author of many technical and popular works in geographical science, meteorology, and climatology.

So far back as 1881, Lieut. Greely, as he then was, took command of an Arctic expedition organised to meet the plan of establishing circumpolar stations in accordance with recommendations adopted at the International Geographical Congress held at Hamburg in 1879. During two years the party, comprising a complement of twenty-five, made their headquarters at Discovery Harbour, Grinnell Land, crossing thence to the Polar Sea and reaching farther north than previously recorded. But disaster attended these pioneers. The vessels of the third relief expedition, which arrived at St. John's, Newfoundland, on July 7, 1884, carried only seven survivors of those who had long been without succour from the outer world in Smith Sound, and had, one by one, succumbed to hunger and hardship. All journals and observational data had been carefully preserved. The Royal Geographical Society recognised Greely's eminent services for science by the award of its Founder's gold medal. The Marquis of Lorne, then president, entrusted the gift at the Society's anniversary meeting in 1886 to Mr. Phelps, the United States Minister, who emphasised that the story of the heroic effort by which the medal had been won would not pass away with his generation, nor perish with the memory of living witnesses; it would remain on the page of history.

PROF. H. BRERETON BAKER selected an experimental theme for his presidential address before the Chemical Society at its annual general meeting on Mar. 22, the title of his discourse being "Constitution of Liquids: some new Experiments." Determinations of the vapour density of liquids which have been dried with phosphorus pentoxide for periods varying from two to ten years show quite clearly that the process of drying results in an increased molecular aggregation; thus the molecular weight of bromine rises from 160 to 242, of benzene from 78 to 126, of carbon disulphide from 76 to 137, of methyl alcohol from 32 to 90, etc. Believing that the molecular aggregation of the bulk of the liquid is even greater than that represented by the vapour density, on account of fractional distillation, Prof. Baker has also developed a modification of Berthelot's method of determining the latent heat of evaporation of a dry liquid, whereby the liquid does not come into contact with the atmosphere. The latent heat for dry benzene per gram was found to be 58 instead of 83, and the boiling-point was 94° C., so that by the application of Trouton's rule the molecular weight of the dry benzene was 136 instead of 78. The view that the removal of water from liquids leads to increased molecular complexity is thus supported by four classes of experimental data, namely, rise of boiling-point, change of surface tension, increase of vapour density, and increase of latent heat of evaporation.

Discussing the reason for these manifestations, Prof. Baker referred to Sir J. J. Thomson's hypothesis of the variation in the attractive force between the constituents of a molecule, due to the proximity of a drop of a liquid with a high specific inductive capacity. Since ionisation favours drop formation, the effect of heating such ionisation-producing substances as lime, thoria, or radium bromide in a reactive gaseous mixture containing traces of water should be to promote combination, an assumption which was found to be justified when a mixture of hydrogen and nitrous oxide was examined in this way. Further, it should be possible, even in the presence of water but in the absence of facilities for its condensation, to stabilise large molecules and to increase the number thereof above that corresponding normally with a given temperature. The application of a potential difference of 400 volts between platinum plates immersed in benzene has, indeed, been found to produce this effect, the benzene then boiling at 92° instead of 79·6°, and having a molecular weight two or three times as great as the normal value; hexane and carbon disulphide behave similarly. Prof. Baker emphasised the preliminary nature of the experiments which he described, but it is evident that if further work on these lines is confirmatory we shall have, for the first time, an explanation of the rôle played by water in changes of molecular association in liquids. Prof. Baker is succeeded in the presidential chair of the Chemical Society by Prof. J. F. Thorpe.

Approximately 550,000,000 acres, or 28·9 per cent. of the total land surface of 1,903,200,000 acres in continental United States, exclusive of Alaska, is classed as forest land. It must not be supposed, however, that the whole of this area produces timber at the present day. The estimate includes vast areas which have been so devastated by careless lumbering and by fires that decades must elapse before they are likely to produce crops of economic value. This class of land includes roughly 81,000,000 acres widely scattered over the country, particularly in the northern and south-eastern States. Of the other 469,000,000 acres, about 80,000,000 acres is woodland, covered with a more or less open stand of poor growth which yields fuel, fencing, and some building material. It is not considered that these areas will ever be capable of producing saw timber on a commercial scale. The productive forest, according to this estimate, covers more than 389,000,000 acres, though this area must have been considerably reduced in the last few years. When the English first settled in the country, three centuries ago, the extent of forest was far greater, especially in the eastern, south-eastern, and central States. About 822,000,000 acres were originally covered with timber forest, and another 1,000,000 acres were lightly wooded with juniper, piñon pine, mesquite, stunted oak, and other species.

These figures are of interest in connexion with the afforestation work now being undertaken in the United States. According to a *Daily Science News Bulletin* issued by Science Service of Washington, the area of the national forests was increased during the past fiscal year by 41,214 acres net. With the separation of the Ocala National Forest, formerly a division of the Florida National Forest, as a distinct unit, there are now 160 national forests in the country, situated in 32 States, Alaska and Porto Rico. The total net gain in national forest area was not so large as in several preceding years, due partly to the fact that a considerable acreage was transferred by special Acts of Congress to national parks. Net reductions in area were shown in Alaska, California, Colorado, Nevada, New York, and South Dakota. The largest increase was in Pennsylvania, amounting to 65,274 acres. Washington was second with 63,084 acres, and Wyoming third with 42,494 acres. The figures demonstrate the scale of the task before the United States if a forest area at all commensurate with the requirements and the consumption of the people is to be built up.

Mr. Francis Rodd has published in the *Times* of Mar. 19 and 20 a brief account of fresh evidence bearing upon the origin of the Tuareg which he has obtained on a recent expedition to Air in the Sahara. This journey was undertaken with the object of investigating the ethnology of these veiled nomads for whom in his previous researches, of which the results were published in 1926, he had suggested the possibility of a derivation from the eastern Mediterranean, and further, that they had moved southward to the Air Mountains from a more northerly position and assumed their characteristic veil somewhere between 600 and 1000 B.C. The evidence now brought to bear upon this question is, in part, that of rock drawings at Air which have now been examined for the first time. The suggested eastern Mediterranean origin was based upon the identification as Tuareg of certain of the Libyans captives in Egyptian paintings and of certain Libyan tribes in Egyptian records from the Fifth to Nineteenth Dynasties as ancestors of the Tuareg on the ground of identity of names. One of the difficulties hitherto felt in the identification, for example, of a Nineteenth Dynasty picture of a captured Libyan chief, has been the fact that a headdress of ostrich feathers is worn instead of the veil. The petroglyphs of Air now show what is apparently an identical headdress. Further, the association of Tifinagh, the Tuareg script, with the petroglyphs, connects them definitely with the Tuareg and not with the previous negroid population of Air. The inscriptions are almost certainly names and patronymics. It follows that so late as the tenth century A.D., the Tuareg, then recently come to Air, were drawing portraits of themselves similar to those drawn by the Egyptians of the Nineteenth Dynasty of the North African peoples west of the Nile.

THE electricity scheme for Central England has now been published. It is the third scheme which the Electricity Commissioners have devised and communicated to the Central Electricity Board. The area covered is more than 7000 square miles and has a population of five million. It extends from Stoke-on-Trent and Mansfield on the north to Tewkesbury and Buckingham on the south, and from Newark and Oundle on the east to Shrewsbury and the Welsh border on the west. There are 46 public generating stations in the area. These include the large stations of the Birmingham Corporation and the stations of the Shropshire, Leicestershire, and West Midlands Power Companies. The problem of the Electricity Board is to consolidate, standardise, and improve these networks. In this area the sale of electricity per head of the population last year was about 146 units. Assuming that the present rate of growth continues, then in 1940 the output will have reached 540 units per head. Of the 46 generating stations in the area, 19 are taken as 'selected' stations. In order that the networks may be most advantageously interconnected by underground cables or overhead wires, it is necessary that the frequency of their supplies should be standardised. The standard frequency is 50, but both the Birmingham Corporation and the Shropshire Power Company generate at 25. It has been agreed to allow for the present the 25 frequency supply to a few generating stations, but when circumstances make it desirable, the change over to the standard frequency will gradually take place. Sir John Snell has stated that from 1925 to 1926 the average price of supply in this area was 1·48*d*. per unit, and that in three or four years it would be less than a penny. It has to be remembered, however, that when large industrial undertakings can be supplied direct from the power-stations through high-voltage lines, the ordinary house consumer has his supply through these lines and in addition through machinery which reduces the pressure and through low-pressure distributing mains. He may look forward to getting his electricity at 3*d*. or 4*d*. a unit, but the industrial consumer may get his at less than ½*d*. per unit.

AT the present time electrical energy is generated in Great Britain mainly in two ways. The first and commoner method is to use steam turbines and coal-fired boilers. The other is done from waste-heat stations which employ gas engines worked from blast furnaces or from coke-oven gas. Sometimes also steam turbines are worked from waste-heat boilers. In a paper read to the Institution of Electrical Engineers on Mar. 15, W. T. Townend pointed out the advantages of combining the production of electrical energy with that of coal by-products. Waste-heat stations are now fairly common on the north-east coast and in the midland mining centre of England. The Electricity Act of 1926 will have a far-reaching influence on the prosperity of the country, as it will doubtless lead to cheaper electricity and to a greater use of the coalfields. There is a possibility of reducing unemployment by encouraging the mining industry to co-operate not only in the supply of fuels but also in that of surplus electrical energy. It has been suggested that if a large increase be made in the quantity of by-products, the world's markets will become saturated and the selling-price would be reduced. If, however, the public be convinced that electricity provides the cheapest and cleanest mode of cooking, there is little doubt that its use would become almost universal. This would save household coal, but hot water would still be required. This could be generated by any well-known type of slow-combustion stove capable of burning coke. Mr. Townend gave other considerations to show that the disposal of coke in the future need not present great difficulties. The attitude of the British Government towards the pretreatment of coal is generally supposed to be that if the process is a success then private capital will be rapidly forthcoming for its development. Mr. Townend thinks it illogical for the coal distillation industry not to be given State support, seeing that by the 1926 Act the State has given guarantees in connexion with the capital required for the 'grid' mains. In his opinion both are for the common good.

THE New Zealand Institute publishes a *Reference List* of the Scientific Periodicals in the Libraries of New Zealand. The list is compiled by Gilbert Archey, the Curator of the Auckland Museum. By co-operation with those in charge of the principal libraries in New Zealand, thirty-one in number, the compiler is able to state, in regard to each of the periodicals indexed, in which libraries the volumes may be found, and whether each set is complete. We are told that certain sets are incomplete, but are not told which are the missing volumes or parts. It would not have been difficult to add this information. The compiler states, however, that the libraries are gradually acquiring the missing volumes needed to complete their sets. The arrangement of the *Reference List* is in the first place geographical by Continents and States in alphabetical order. It is only within each country that the references are arranged according to subjects. It would have been much more convenient had the various sciences been taken as the primary subdivisions. As the list stands, it will be difficult for anyone to be sure that he has found all the periodicals dealing with a particular subject. As an example: An entomologist will find 37 journals devoted to entomology distributed under the headings United States, Hawaii, New York, Belgium, France, Germany, Great Britain, Italy, Russia and Switzerland. But without careful scrutiny, he will never be certain that he has not overlooked some entomological journals. We congratulate the Curator of the Auckland Museum, however, on a useful piece of work carefully executed.

THE Department of Entomology of the British Museum (Natural History) has received from Capt. K. J. Hayward, of Villa Ana, Argentina, a fine specimen of *Megasoma janus*, one of the giant horned beetles, of which it is believed that only two examples, both imperfect, have ever before reached Great

Britain. The legs of this insect, when fully extended, cover a space of about six inches from front to rear. Acquisitions in the Department of Geology include type-specimens of Carboniferous Corals from Yorkshire, presented by Prof. R. G. S. Hudson; three plaster casts of type-specimens of starfishes from the Lower Devonian, near Goslar, presented by the Director of the Preussische Geologische Landesanstalt, Berlin; type and figured specimens of Ammonites from the Gault of Southern England, presented by Dr. L F. Spath. The most important recent addition to the mineral collection is a set of very large specimens of crystallised spar from the Snailbeach mine near Minsterley, Shrewsbury, bequeathed by the late Mr. William Oldfield. They were set up in his garden, but not having been piled up to form a rockery or built into walls, as is often the fate of such specimens, the crystals have not been bruised and damaged. The eight specimens, with a total weight of just over 23½ cwt., consist of slabs measuring up to 5 ft. 6 in. by 3 ft. 6 in. These are covered with two-inch cubes of galena, together with smaller crystals of zincblende and copper-pyrites. Only in exceptional cases are specimens of this size raised, for they have no metal value.

AN important development of research in the Antarctic regions is announced in the *Norges Handels og Sjöfartstidende* for Feb. 18. Consul Lars Christensen has decided to establish a radio and meteorological station on Bouvet Island, with the co-operation of the Norwegian Meteorological Institute. This will be an important step in the direction of carrying out Mr. R. C. Mossman's plan for supplementing the South Orkneys meteorological station (established by him on Dr. Bruce's *Scotia* expedition in 1903 and taken over by the Argentine Meteorological Department) by similar permanent observatories on Bouvet Island, the Crozets, and Kerguelen. The same paper says that the cruise of the *Norvegia* towards Enderby Land has had to be postponed, as the damage the vessel received off Bouvet Island cannot be repaired in time for the present Antarctic summer. The *Norvegia* found that the Falkland Island seal (*Phoca Falklandica*) still breeds on Bouvet Island, though it was practically exterminated in its original haunts by the sealers of a hundred years ago.

WE have recently received from the Section of Geodesy of the International Union for Geodesy and Geophysics several issues (Nos 8, 10-13) of its organ (nominally issued quarterly), the *Bulletin Géodésique*, for the years 1925–1927. They represent a considerable and very useful addition to the literature of international interest to workers in the subject. They contain papers, mainly printed in French, on theoretical and instrumental questions, reports on work executed or projected in the various parts of the world, biographical notices and bibliographies, and a chronicle of current events relating to the science. Among the principal general topics dealt with in the issues named are questions connected with an international ellipsoid of reference; the centre of gravity and the moments of inertia of the oceans; the mean density of the earth; errors in high-precision levelling; and an international inquiry (with answers to a questionnaire) on the trustworthiness of invar wires and tapes.

THE annual report of the Smithsonian Institution of Washington for the year ending June 30, 1926, which has recently been issued, is presumably the last of the long series of these volumes to bear the name of the late Dr. C. D. Walcott. We have already referred to the presentation of this report (NATURE, April 2, 1927, p. 505) and it will be sufficient to direct attention to the valuable general appendix, which, as usual, accompanies the published report. This appendix consists of no less than thirty-one articles, some of them reprints of recent papers and others original, among those of general interest we may mention the papers by Dr. J. H. Jeans on the new outlook in cosmogony, Dr. C. G. Abbot on the influence of the sun's rays on plants and animals, M. Lucien Rudaux on conditions on the moon and the planets, Prof. R. A. Millikan on cosmic rays, Prof. E. Newton Harvey on 'cold' light, Dr. Arthur D. Little on carbon, Dr. John M. Coulter on the history of organic evolution, Dr. L. O. Howard on the control of injurious insects by parasites, and obituary notices of the late Dr. W. Bateson, by Prof. T. H. Morgan, and of Prof. Kamerlingh Onnes, by Dr. F. A. Freeth, the latter being reprinted from NATURE.

THE Ministry of Agriculture and Fisheries has just published a small volume on "Poisonous Plants of the Farm," by H. C. Long (*Miscellaneous Publications, No. 57*, London: H.M. Stationery Office. 2*s*. net). Though the number of wild plants which are seriously poisonous is perhaps small compared with the total number of species included in the British flora, yet there are many of very common occurrence which may occasionally cause serious losses to farm stock, and also illness and death to human beings, particularly children. In cases where poisonous plants occur in quantity, they may be unavoidably harvested, and later given to stock, or they may be eaten in the green state in the open fields or along the hedgerows. There are also numerous cultivated plants and trees which are poisonous and often responsible for trouble with live stock. Sometimes the effect is merely irritant, sometimes it is poisonous. Mr. Long deals with a large number of species, and the toxicology of each is discussed in a simple way. The book is written in non-technical language, is well illustrated by many full-page illustrations, and should be widely welcomed by farmers and those engaged in agricultural instruction.

THE estimates for Civil Services (Class IV., Education, Science, and Art) for the year ending Mar. 31, 1929, include the sum of £225,085 for scientific investigation, etc., and £1,579,400 for Universities and Colleges, Great Britain, and Intermediate Education, Wales.

A VERY large earthquake was recorded at Kew Observatory on Mar. 22 at 4 hr. 29 min. 17 sec.

G.M.T. The epicentre is estimated to have been 5780 miles away, and was probably near the Pacific Coast of Mexico. This disturbance was the most violent shock which has been recorded at Kew since the great Chinese earthquake of May 22 of last year.

THE last meeting of the one hundred and twenty-sixth session of the Royal Philosophical Society of Glasgow was held on Mar. 21. Prof. Graham Kerr, in vacating the president's chair which he had occupied for three years, reviewed the work of the session, and intimated that as great interest in the Society had been shown by women by reading papers and by attending the meetings, it had been agreed that their interest should be recognised by welcoming women to full membership. The following officers were then elected: *President*, Mr. George A. Mitchell; *Vice-Presidents*, Prof. Peter Bennett and Dr. Henry L. G. Leask; *Hon. Treasurer*, Sir John Mann; *Hon. Librarian*, Dr. James Knight; *Hon. Secretary*, Dr. Charles R. Gibson; *Hon. Auditors*, Mr. Alex. Murdoch and Mr. David A. Richmond; *Acting Secretary*, Dr. James M. Macaulay.

AT the annual general meeting of the Ray Society, held on Mar. 22, the following officers were re-elected: *President*, Prof. W. C. McIntosh; *Treasurer*, Sir Sidney F. Harmer; *Secretary*, Dr. W. T. Calman. Mr. J. Spedan Lewis was elected a vice-president, and Mr. D. J. Scourfield and Mr. A. W. Sheppard were elected new members of council. It was announced that the first volume of Dr. T. A. Stephenson's "Monograph of the British Sea-Anemones" would shortly be issued to subscribers for 1927. The year 1927 being the tercentenary of the birth of John Ray, the Council has accepted the offer of Dr. R. T. Gunther to prepare, as a commemorative volume, a series of unpublished letters of Ray which are preserved in the Bodleian Library and in the British Museum. This volume is in the press and, together with the third and final volume of Messrs. Soar and Williamson's "British Hydracarina," will form the issue for 1928.

AT the annual general meeting of the Institute of Chemistry, held on Mar. 1, the Meldola Medal for 1927 was presented to Dr. J. H. Quastel, fellow of Trinity College, Cambridge. In making the presentation, Mr. E. R. Bolton, vice-president of the Institute, said that Dr. Quastel has advanced the knowledge of reduction–oxidation systems following on the pioneer work which resulted in the discovery of glutathione by Sir Frederick Gowland Hopkins, and has introduced new methods into the study of living cells as represented by bacteria. He has also thrown some light, for the first time, on the mechanism of the activation of molecules by a living organism. It will be recalled that the Meldola Medal is presented by the Society of Maccabæans in commemoration of Prof. Raphael Meldola, president of the Institute of Chemistry (1912–15) and of the Society of Maccabæans (1911–15), and is awarded for meritorious work in chemistry during the year.

THE ninety-sixth annual meeting of the British Medical Association will be held at Cardiff on July 20–28, under the presidency of Sir Ewen Maclean, who will deliver his address on the evening of July 24. The annual exhibition of surgical appliances, foods, drugs, and books will be open on July 23–27. A pathological museum is also being arranged by Drs. J. B. Duguid and J. Mills, Department of Pathology and Bacteriology, Welsh National School of Medicine, The Parade, Cardiff. The following presidents of sections are announced in the provisional programme: Sir Thomas Lewis (*Medicine*), Prof. A. W. Sheen (*Surgery*), Dr. T. Watts Eden (*Obstetrics and Gynæcology*), Prof. E. H. Kettle (*Pathology and Bacteriology*), Dr. E. Goodall (*Mental Diseases and Neurology*), Sir John Lynn-Thomas (*Orthopædics*), Dr. A. Howell (*Diseases of Children*), Mr. F. P. S. Cresswell (*Ophthalmology*), Dr. D. R. Paterson (*Laryngology and Otology*), Dr. H. M. Davies (*Tuberculosis*), Dr. O. L. Rhys (*Radiology and Physio-Therapeutics*), Dr. E. C. Williams (*Preventive Medicine*), Mr. R. M. F. Picken (*Public Health*), Dr. W. E. Thomas (*Medical Sociology*), Dr. Philip H. Manson-Bahr (*Tropical Medicine*), Mr. Walter G. Spencer (*History of Medicine*), Dr. W. Langdon Brown (*Therapeutics and Pharmacology*), Sir Robert Bolam (*Dermatology*). The honorary local general secretary for the meeting is Dr. G. I. Strachan, 20 Windsor Place, Cardiff.

THE Ministry of Health has published the Seventh Report of the Advisory Committee on the Welfare of the Blind, 1926–27. The returns show that there were 46,822 blind persons in England and Wales in 1927. Much information is given on the education and employment of the blind, their distribution in administrative districts and by age periods, their earnings, grants for their welfare, etc.

Bulletin No. 59 (1927) of the National Research Council, Washington, contains in five papers the report of a committee on chemiluminescence. The facts and theories of this extensive subject are conveniently summarised in the report, and are discussed from various points of view ranging from the purely physical to the biological. The members of the committee and authors of the papers are E. Q. Adams, A. D. Garrison, A. H. Pfund, and H. S. Taylor, under the chairmanship of E. N. Harvey.

The new volume of *Ergebnisse der exakten Naturwissenschaften* (No. 6), published by Julius Springer, Berlin (price 24 gold marks), contains articles on the structure and development of stars, by Prof. Vogt; on the sources of stellar energy, by Prof. Freundlich; on photometry, by Prof. Brodhun; on ferromagnetism, by Dr. Steinhaus; on the optical determination of the heats of dissociation of gases, by Dr. Sponer; on adsorption, by Dr. Cassel; on the equation of state for solids, by Dr. Braunbeck; on the theory of strong electrolytes, by Dr. Orthmann; on active hydrogen, by Dr. Boenhoffer; on the element rhenium, by Drs. I. Tacke and W. Noddack; and on photographic methods of measurement, by Mr. P. Seliger. Most of the sections have a bibliography of other literature dealing with the same subject, and the volume includes in addition the index for the present and five preceding issues.

A catalogue of nearly 400 second-hand works, mainly on natural history subjects, but some on historical medicine and on mechanical arts, has just been circulated by Mr. J. H. Knowles, 92 Solon Road, S.W.2.

The industrial uses of sand are numerous and varied. Those interested will welcome a new edition of the trade catalogue of sands, which include certain clays, flint, and other non-metallic minerals, issued by Mr. A. L. Curtis and obtainable from him (price 1*s.*) at Westmoor Laboratory, Chatteris.

An important catalogue of some 1500 works relating to Australia, Tasmania, New Zealand, and the Islands of the Pacific Ocean has been received from Messrs. Francis Edwards, Ltd., 83 High Street, Marylebone, W.1. Included are many rare volumes, and a series of original water-colour drawings of Sydney and its Harbour, by Conrad Martens.

Applications are invited for the following appointments, on or before the dates mentioned :—Two junior assistants under the Safety in Mines Research Board, for research, respectively, in connexion with colliery wire ropes research, and on materials and structures used for the support of underground workings—The Under Secretary for Mines, Establishment Branch, Mines Department, Dean Stanley Street, S.W.1 (April 7). A temporary demonstrator in pharmacy, and an assistant lecturer in preparing, combing, and spinning, and yarn manufacture, at the Bradford Technical College—The Director of Education, Town Hall, Bradford (April 11). A secretary to the Institution of Municipal and County Engineers—The Secretary, Institution of Municipal and County Engineers, 92 Victoria Street, S.W.1 (April 11). A professor of anatomy in the University of Lucknow—The Registrar, The University, Lucknow, India (April 23). A professor of engineering in the University College of South Wales and Monmouthshire—The Registrar, University College, Cardiff (April 28). A lecturer in geography at Birkbeck College—The Secretary, Birkbeck College, Breams Buildings, Fetter Lane, E.C.4 (May 1). A senior lecturer in zoology in the University of the Witwatersrand, Johannesburg—The Secretary, Office of the High Commissioner for the Union of South Africa, Trafalgar Square, W.C.2 (May 4). A lecturer in mathematics at Armstrong College—The Registrar, Armstrong College, Newcastle-upon-Tyne (May 5). A senior entomologist for noxious weeds investigation, a senior entomologist for noxious insects investigation, and a senior entomologist at Canberra for advice and technical assistance in various branches of investigation and to take charge of the museum. Each post under the Entomological Section of the Australian Council of Scientific and Industrial Research—F. L. McDougall, Esq., Australia House, Strand, W.C.2 (May 31). A professor of therapeutics, pharmacology, and materia medica, at University College, Galway—The Secretary, University College, Galway (June 15). A research chemist for work in connexion with fastness tests for dyed materials—The Secretary, Colour Supervisory Committee, British Research Association for the Woollen and Worsted Industries, Torridon, Headingly, Leeds. A lecturer in estate management subjects at the Royal Agricultural College, Cirencester — The Principal.

Our Astronomical Column.

Comets.—M. Giacobini, who is already known as the discoverer of twelve comets, including two short-period ones, but whose name has not appeared in the list of discoverers since 1907, reports a new comet of the eleventh magnitude, the position of which on Mar. 17, at 22 h. 14 m. U.T., was R.A. 5 h. 50 m. ; N. Decl. 14° 35′; rapid motion southward. It would appear that the discovery was made by photography, and that the image was not noticed for some days. It is to be feared that there may be some difficulty in locating the object, without more definite knowledge of its motion.

The following is the latest position to hand of Reinmuth's Comet (1928*a*), made at Babelsberg by G. Struve :

Mar. 19 d. 22 h. 19 m. 24 s. U.T., R.A. (1928·0) 9 h. 18 m. 28·60 s., N. Decl. 23° 35′ 5·5″.

Prof. A. O. Leuschner suggests the possible identity of this comet with that of Taylor (1916 I). There are considerable difficulties in accepting this, but it must be remembered that Taylor's comet divided into two portions, like that of Biela. This brings a measure of uncertainty into the forecasts of its motion. Mr. F. R. Cripps found next October as the probable date of perihelion of Taylor's comet (*B.A.A. Handbook*, 1928).

Oscillations in the Period of Beta Lyræ.—Miss M. A. Blagg contributed papers on this star to the *Mon. Not. Roy. Ast. Soc.*, vols. 84 and 85 (1924 and 1925). These announced the detection of a long-period fluctuation in the time of minimum, taking more than nine years to complete its cycle. She contributes a further paper on the subject to the January number of *Monthly Notices*, in which she utilises additional material derived from observations by Rev. J. G. Hagen, Mr. E. F. Sawyer, and several members of the Variable Star Section of the B.A.A. The result confirms her previous conclusions, with slight alterations in the numerical values. Her formula for principal minimum is $2398590{\cdot}57 + 12{\cdot}908006\,E + 0{\cdot}000003914\,E^2$. On this is superposed a B wave given by $2407136{\cdot}12 + 6{\cdot}584\,E + 0{\cdot}00000308\,E^2$. It will be noticed that the period of this wave is nearly, but not exactly, half that of the main wave, and that both periods are increasing, as shown by the terms in E^2.

Allusion is made in the paper to a research by S. Tcherny in *Ast. Nach.* of May last, in which he finds by theory a fluctuation of 3439·543 days, which is within 3 days of Miss Blagg's period. His suggestion is that rotation is not quite synchronous with revolution, which produces a gradual change in the presentment at minimum. The research is a hopeful one for finding out more about the exact circumstances of this interesting star. Now that the phenomenon is known, observations can be made more systematic than before. They were sometimes missing at critical stages.

Research Items.

Excavations at the Hippodrome, Constantinople.—Mr. S. Casson in *Discovery* for March surveys the progress which has been made in the excavation of the Hippodrome at Constantinople in the two seasons since work was first begun. His task was complicated by the fact that the dimensions of the building were entirely unknown, and estimates by experts of its extent varied by hundreds of feet. All that was left visible were the three monuments down the centre, one of them the bronze serpent column which celebrated the Greek victory over the Persians at Platæa in 479 B.C., and was brought from Delphi by Constantine. It is interesting to note that an examination of these three monuments, of which two, the Column of Constantine Porphyrogenitus and the Serpent Column proved to have been used as fountains, revealed that the spina or dividing wall, which, it had been held, must run down the centre of the Hippodrome and upon which the monuments were supposed to stand, had no existence. In the Sphendone, the substructure at the end of the building, which was originally used for storing apparatus and animals for the games, were found twenty-five chambers, each opening out of a wide corridor which ran the length of the building. These in later and more troubled time were converted into cisterns for storing the water-supply, a purpose for which part is still used. The excavations here made it possible to determine the width of the building as 117·5 metres. Trial excavations to determine the length, brought to light a building which is probably the Baths of Zeuxippos. The total length was found to be 480 metres. A Turkish wall composed almost entirely of marble fragments from the Hippodrome furnished material from which it has been possible to reconstruct a general idea of what the Hippodrome looked like.

Milk Pasteurisation and the Tubercle Bacillus.—Many investigations have been made on the thermal death point of the tubercle bacillus in milk, but owing to the difficulty of obtaining satisfactory samples of naturally infected milk, a large proportion of the experiments have been carried out with artificially infected milk. Mr. L. J. Meanwell has recently conducted a research into the effect of pasteurisation in destroying the tubercle bacillus in naturally infected milk. It was found that a temperature of 62·8° C. (145° F.) acting for 30 minutes does not invariably kill the tubercle bacillus, though in most cases it is effective (*Jour. Hyg.*, vol. 26, p. 392; 1927). The temperature and time are those commonly employed in pasteurisation, but the apparatus used consisted of a vessel containing only about 1000 c.c. of milk, heated in a water-bath, and we still seem to lack experimental information of the efficiency of a *commercial* pasteurising plant for destroying the tubercle bacillus in naturally infected milk.

West African Myriapoda.—Ralph V. Chamberlin has described the Chilopoda and Diplopoda collected by the American Museum of Natural History Congo Expedition (*Bull. Am. Mus. Nat. Hist.*, **57**, pp. 177-249; 1927). The west African Diplopod fauna is rich and varied and largely a distinct and peculiar one. As was to be expected, it proves to have little in common with the north African fauna, and it is also now certain that it has little similarity to the fauna of east and south Africa. With the exception of five species of widespread chilopods, no species are common to east and west Africa, and many of the west African genera are likewise peculiar, such as all those constituting the family Prepodesmidæ as well as many other polydesmoids and certain spirostreptoids. Noteworthy is the apparently complete lack in the west African fauna of any representatives of the Oniscomorpha, members of which are common in south Africa as well as in Asia and Australia.

Hybrids between Species of Unio.—When, two years ago, A. S. Kennard, A. E. Salisbury, and B. B. Woodward published (*Proc. Malac. Soc. Lond.*, vol. 16) the first part of their monograph on the "British Post-Pliocene Unionidæ," they described a form of Unio which in their opinion could only be a hybrid between *Unio pictorum* (Linn.) and *U. tumidus*, Retzius. All that was then known was that the specimen was British and had been in the possession of the well-known dealer, W. Rich. Since then the non-marine portion of the late P. B. Mason's collection has passed into the hands of A. S. Kennard and proved to contain a series of similar Unios coming from Repton Park, Derbyshire (*Proc. Malac. Soc. Lond.*, vol. 17), and since Mason was shown to have been in correspondence with Rich, there is no doubt as to the identity of the locality of the first described specimen. The interesting point is that whereas the two species are frequently found dwelling together, no case of hybridisation has hitherto been recorded. Out of the 89 specimens of Unio from Repton Park, 31 being normal *U. pictorum* and 25 normal, with 14 malformed *U. tumidus*, there were 19 hybrids. These last, whilst showing individually a mixture of the characters of the two parent species, could not be sorted out into classes, or analysed into Mendelian factors. The authors tabulate the varying combinations of characters in 15 of the examples and figure both these and the normal forms very fully on thirteen photographic plates, which they were enabled to do (in this as in the first part) by aid from the Government Publication Grant administered by the Royal Society. In an appendix, H. H. Bloomer describes the present condition of the locality. In both parts of their monograph the authors make an important departure in employing the internal characters of the shell instead of relying, as usually the case with other writers, on the extremely variable external form for purposes of distinction, whilst at the same time stressing the value of the umbonal ridges.

Production of Polyploid Plants.—The Solanum chimæras of Winkler, produced by cross-grafting, are well known. Some of these gave rise to tetraploid forms, but the latter were rare—only three among several thousand Mr. C. A. Jorgensen (*Jour. of Genetics*, vol. 19, No. 2) has now found that the grafting is unnecessary and that tetraploid and occasional triploid shoots will appear when plants of various Solanum species are simply decapitated and allowed to regenerate. He points out the not infrequent occurrence of binucleate tissue cells in plants and attributes the origin of tetraploid shoots to the fusion of the two nuclei in such cells during mitosis, a process which he calls endo-duplication. Haploid *Solanum nigrum* has also been obtained by pollinating it with *S. luteum*. The sperms from the foreign pollen tubes enter the egg cell and there disintegrate, while the egg develops parthenogenetically. Apparently the number of chromosomes is usually doubled later in the embryo, for 28 diploid and 7 haploid plants of *S. nigrum* were obtained in this way, and a single true hybrid with *S. luteum*. The various heteroploid forms obtained are compared with each other morphologically, many of the differences, *e.g.*, in flower size, leaf-shape, and pollen grains, corresponding to those already known in polyploid Œnotheras and Daturas. Some of the work was done in conjunction with Mr M. B. Crane. It is interesting that in the haploid *S. nigrum*, which has 36 chromosomes, these show some pairing in meiosis, such as occurs in triploid hybrids. This suggests that the hexaploid *S. nigrum* may have arisen as a hybrid between a diploid and a tetraploid species, which afterwards doubled its chromosomes.

Shore Line Topography.—A striking phenomenon on the shores of many of the English lakes is the line of large boulders ranged along the water's edge with a remarkable uniformity of line. Their position has been explained as that of the heavy part of the detritus rolling down the slopes to the lake, which stops with the reduction of gradient on the beach. But in a lecture to the Royal Geographical Society on the shore topography of the English lakes on Mar. 12, Mr. T. Hay amplified this explanation, which he has found untenable in those lakes which have gentle slopes around them. A striking example is the western side of Ullswater between Glencoin and Gowbarrow. The boulders are clearly of glacial origin and are the remnants of a moraine of which the lighter materials have been carried away by wave action. Thus they are the rocky skeleton of a vanished strip of hillside, and so are regularly arranged on the beach Another type of shore lake to which Mr. Hay directed attention is marked by rounded protuberances of boulder clay projecting into the water like delta fronts. They are, however, not deltaic in origin, but are due to the cutting action of the waves on stretches of boulder clay that have not been subjected to excavation by running water. At the mouths of streams, except where deltas grow, the coast lines tend to show great landward bites as the waves have an easier task in excavation.

Survey of St. Kilda.—Mr. J. Mathieson, who, with Mr. A. M. Cockburn, spent five months on St. Kilda last year while engaged in a survey of the island, has received the great compliment of having his work accepted by the officials of the Ordnance Survey, who have published his map of the main island and neighbouring islets as a sheet of the 6 in. to 1 mile map. The sheet shows as an inset the village and landing-place on the scale of 1/2500. Copies of the map are being distributed with the issue of the *Scottish Geographical Magazine* for Mar. 15, which contains an article by Mr Mathieson on the group, accompanied by notes on the geology by Mr. A. M. Cockburn, the flora by Mr. John Gladstone, and the birds by Mr. Seton Gordon. The article is illustrated by a very fine series of photographs, those showing the magnificent cliffs of the island being particularly impressive. It gives an authoritative account of all the objects of interest in the group, and includes notes on the inhabitants, who now number 48 in all. Though the island is often visited during the summer season and has been the subject of various investigations, it has never before been surveyed accurately and in detail. It will be a source of general satisfaction in Scotland that this long-delayed survey has now been carried out entirely by unassisted individual effort, and yet with a care which has received official recognition and acceptance. The publication of Mr. Mathieson's photographs and description also add greatly to the value and interest of the map.

Geology of British Guiana.—A valuable contribution to our knowledge of the country north and south of the famous Kaieteur Falls has been made by Smith Bracewell in his "Report on the Preliminary Geological Survey of the Potaro-Ireng District of British Guiana" (*B G. Combined Court*, No. 21/1927). The falls have a vertical drop of 740 feet at the head of a sixteen-mile gorge cut in the great scarp of the Kaieteur Sedimentary Series The latter consists of shale, conglomerate, and sandstone, and lithologically the series can be matched with similar Brazilian beds ranging in age from Devonian to Triassic. In the absence of fossils no closer comparison is possible. The remarkable association of diamond-bearing alluvium with the edge of the scarp suggests that the diamonds are probably derived from the Kaieteur conglomerate The whole region of the plateau is injected with thick sills and dykes of gabbros, norites, and dolerites which resemble the post-Triassic intrusions of Brazil. It has been thought that these may have been in some way responsible for the diamonds, but the associations of the latter do not support this view. They do, however, seem to have contributed to the gold resources of the district, for auriferous aplites occur which are specially rich near contacts with the later basic rocks. Below the escarpment the basement rocks, like those of the Brazilian shield, include a great variety of gneisses and schists and granites. Highly folded sedimentary formations trending north and south also occur. Economically, the study of the country justifies increased optimism as regards the mineral resources and their successful exploitation.

A Work-Meter.—Messrs. Lewenz and Wilkinson, Ltd., of 25 Victoria Street, S.W.1, have sent us a pamphlet describing their 'work-meter.' This instrument is an electrical recording mechanism which registers continuously by means of a 'time-space' graph the performance of any machine to which it is connected. The chart shows at any moment whether the machine is working at full output or not, while the complete chart enables the production efficiency of the machine to be computed. In this way an accurate record can be obtained of the working of every machine in the factory, and thus the engineer can control the speeds so as to get the maximum economy.

The Estimation of Firedamp.—The most convenient method for the estimation of firedamp in coal mines is still the observance of the 'cap' which it produces on the flame of a safety-lamp. Different types of lamp show different heights of cap for the same amount of firedamp, and hence it is necessary to issue a series of pictorial reproductions of the flame-caps to be expected with any given type. Existing methods of obtaining these pictures have proved unsatisfactory and a new process is described in *Paper No. 37* of the Safety in Mines Research Board (London: H.M. Stationery Office). This method is photographic, the prints finally obtained being dyed a deep blue The paper contains a number of reproductions of such photographs.

Rare Earth Materials and Element No. 72.—Since zirconium and thorium are closely related to element No. 72 (hafnium or celtium) and are frequently found in rare earth materials, it would seem probable that element No. 72 should also be present in these minerals. W. B. Holton and B. S. Hopkins have therefore examined the most soluble fractions of fractional crystallisations of materials of the yttrium group by X-ray analysis. These fractions contained most of the thorium and zirconium, but it was found that the concentration of element No. 72 was not greater than 1 part in 1000 Various rare earth materials, including gadolinite from Norway, were also investigated by photographing their arc spectra, but only in one case were indications of the presence of hafnium found.

THE SEPARATION OF OIL FROM CONDENSATION WATER BY ELECTROLYSIS.—Most of the oil which is used for the lubrication of steam pistons and gearing is atomised and carried away in the waste steam. This causes a milky emulsion, which is very stable, to form on the condensed water. Even after standing a long time the separation of the oil from the water is very imperfect. Were it not for this, it would be equal in quality to distilled water, and would be most useful for manufacturing purposes as well as for feeding the boiler. Mechanical oil separators are only moderately successful, and when the condensed water is used for the boiler, appreciable quantities of oil pass into it. With hard water this combines with the boiler scale to form a solid mass which settles on the walls of the boilers and leads to overheating of the plates. In *Helios* for Jan. 29, Fritz Hoyer describes how electrolysis has been successfully employed to purify condensed water. A direct electric current passes through the water, collects the oil in foamy flakes, destroying the emulsion, and so renders filtration possible. The consumption of energy is about one kilowatt hour for five cubic metres of water. The apparatus is automatic, no special attendance being required.

POZZOLANAS.—*Bulletin No. 2* of the Building Research Station of the Department of Scientific and Industrial Research (London: H.M. Stationery Office) deals with the subject of pozzolanas. A pozzolana is a substance which is mixed with lime mortar in addition to, or in partial substitution for, sand, in order to increase the strength of the mortar. To achieve this, the pozzolana must be capable of combining with hydrated lime in the presence of moisture to form insoluble compounds which act as cements. The use of such substances was the so-called secret of the old Roman builders, and Vitruvius mentions the use of volcanic ash for this purpose. Other suitable natural materials are trass, a volcanic rock found in Germany, and various forms of diatomaceous earth (such as kieselguhr) or 'celite' as it is termed in the United States. Artificial pozzolanas are also employed, the more important being burnt clay, granulated slag, certain clinkers, and spent oil shale. The pozzolana reacts with the lime to form insoluble silicates and aluminates and hence pozzolanic mixtures can set under water, and in the absence of carbon dioxide, the presence of which is essential for the hardening of ordinary mortars. Such mixtures are also more resistant to sea water and acid, but the time required for effective setting varies enormously according to the nature and degree of fineness of the pozzolana.

NITROGEN FIXATION.—Prof. G. Senn, of Basle, has published a very useful review of the work on which our present knowledge of the assimilation of atmospheric nitrogen by lower plants is based (*Biol. Reviews*, vol. 3, No. 1, 1928, and also in *Verh. d. Schweiz. Naturf. Gesell.*, Jahresversammlung 108, 1927). One merit of the work is that it takes account of several continental researches not often cited in British lists of references on the subject. Besides the well-known free-living and symbiotic bacteria which fix free nitrogen, attention is directed to several species of fungi which perform the same function. The number of known forms of these nitrogen-fixing fungi has been increased by the work of some of Dr. Senn's pupils. Some controversial points regarding the energy relations of nitrogen fixation emerge from this paper. From the data of Ternetz and others, nitrogen fixation is regarded as a function requiring free energy, which can be procured by the respiration of large quantities of carbohydrates. Recently, the energy relations of nitrogen fixation have been carefully worked out by Dean Burk, and his results are published in a paper not noted by the present author (see *Jour. Gen. Physiol.*, vol. 10, No. 4). Burk finds that fixation of nitrogen even with liberation of energy will take place if either oxygen or hydrogen or other substances, the standard free energies of which are close to zero, are involved in the formation of either nitrates, ammonia, or other compounds. It is pointed out that there are two, and only two, general conditions where nitrogen fixation can require energy. These are, first, if nitrogen reacts with some compound like water with an already high negative free energy of formation and where negligible oxidation of nitrogen takes place; secondly, if the metabolism of the plant is not carried on at the concentrations where the process would yield free energy.

THE PRESSURES PRODUCED BY ELECTRIC ARCS IN CLOSED VESSELS.—A paper (No. 39) by G. Allsop and R. V. Wheeler, published by the Safety of Mines Research Board (London: H.M. Stationery Office), describes the results of experiments on the pressures produced by arcing in closed vessels during switching operations. When a disruptive electric discharge occurs, a pressure wave or pressure pulse is undoubtedly produced. But as disruptive discharges in air at voltages less than 350 are impossible, it was of importance to find out whether the arcs formed when breaking the circuit necessarily produced a pressure wave. In the first set of experiments the enclosure had a volume of 10·8 cub. in., the supply voltages varied from 220 to 260, and the currents from 12 to 136 amperes. The mean power expended in the arc varied from 0·38 to 5·88 kilowatts, and its duration from 0·4 to 0·6 of a second. The pressure in pounds per square inch increased fairly regularly with the power from about 1 to 12. Experiments with a voltage of 570 and with alternating voltages were also made. The results show that with voltages up to 250 and currents up to 200 amperes, no pressure wave could be detected. With 1350 amperes at 575 volts, no pressure wave was detected by a manometer situated six inches from the arc. Dangerous pressures are only produced when the arcing is prolonged. For example, a ¼-in. arc lasting for half a second gave rise to a pressure of 140 lb. per square inch. It is also clearly shown by the experiments that when alternating currents are used, the arcing effects are much less severe. Dangers from rise of pressure as the result of arcing are much greater with direct than with alternating currents.

THE NATURE OF ACTIVE NITROGEN.—Further information concerning the nature of active nitrogen and obtained by a study of the synthesis of ammonia from the elements is described by B. Lewis in the *Journal of the American Chemical Society* for January. It can be shown that the formation of ammonia from mixtures of unactivated nitrogen and atomic hydrogen, activated nitrogen *molecules* and atomic hydrogen, or active nitrogen and unactivated hydrogen, involves more than two successive and selective collisions. With *atomic* nitrogen and atomic hydrogen only two collisions would be required: $N + H = NH$; $NH + H_2 = NH_3$. The results obtained appear to show that ammonia is formed only when active nitrogen and atomic hydrogen are mixed, and, with the assumption that no tri-atomic hydrogen is present, it is inferred that active nitrogen contains atomic nitrogen.

Vitamin B.

ALTHOUGH our knowledge of the constitution and nature of vitamin D is greater than our knowledge of the chemical composition of the other accessory factors, recent work suggests that it will not be long before it has advanced to a comparable stage. Progress has been particularly striking in the case of vitamin B, and has followed two lines: the physiological function of this compound in the animal economy has been investigated by a number of observers, whilst at the same time much information has been obtained as to its chemical nature and properties.

In this connexion the most important recent development is the confirmation of suggestive previous researches, which indicated that the substance which we call 'vitamin B,' consists of at least two compounds with different chemical properties and different physiological functions. In this point vitamin B is following the example set by vitamin A, and although at first sight this splitting of a compound of unknown chemical constitution into two similarly unknown bodies may seem to hamper further advances, yet the opposite is probably more nearly true, at any rate if we may take the differentiation of vitamin D from vitamin A, followed by the early recognition of the sterol nature of the former, as an example of what may be expected to occur in the future in the case of vitamin B.

Our present knowledge indicates that deficiency of vitamin B in the diet is associated with human beriberi and pellagra and avian polyneuritis: the latter disease is usually held to be the equivalent of human beriberi. The association of pellagra with deficiency of vitamin B has only recently been conclusively demonstrated by Goldberger and his co-workers. How a deficiency of the vitamin produces symptoms is not known, although many suggestions, based on experimental work, have been made. Recent investigations into its physiology have included both a direct attack on the problem and also an examination of its relationship to the three chief classes of foodstuffs, the proteins, fats, and carbohydrates, in the diet.

J. C. Drummond and G. F. Marrian (*Biochem. Jour.*, vol. 20, p. 1229; 1926), after a scrutiny of the literature, found that the only definite function attributed to vitamin B was that of stimulating tissue oxidations, based on a decrease in oxidative power of the body in conditions of vitamin deficiency. In a series of experiments the authors investigated this alleged function and definitely demonstrated that vitamin B bears no relationship to tissue oxidations. Thus muscles obtained from pigeons or rats suffering from vitamin B deficiency, decolorised methylene blue under anaerobic conditions to the same extent as the equivalent muscles from normal birds or animals: and the oxygen consumption of pigeon breast muscle or liver was the same, whether the tissue had been obtained from normal birds or from those suffering from polyneuritis. The oxygen consumption of rats kept on a complete diet was compared with that of animals kept on a vitamin B deficient diet, and no difference between the two was detected until the rats in the latter group were almost moribund: for these experiments the animals were lightly anæsthetised with amytal to eliminate variations in the oxygen consumption due to movements and placed in a modified form of the closed-circuit type of apparatus for estimating the respiratory exchange.

Now the early symptoms of vitamin B deficiency in the animals used by Drummond and Marrian are loss of appetite, constipation, and lassitude: the last stage of lowered body temperature, laboured respirations, inco-ordination of the hind limbs and convulsions only lasts about twenty-four hours, and the fall in oxygen consumption is only observed when the body temperature has fallen below 33° C: if the animal is warmed up, the body temperature and the oxygen consumption return towards their usual level, with a temporary improvement in the animal's condition. These effects, however, are not peculiar to vitamin B deficiency itself, but occur in animals starved completely of food or kept undernourished on a complete diet, the fall in body temperature and oxygen consumption occurring as above as a terminal event.

The conditions of starvation and vitamin B deficiency also produce similar effects on the blood sugar, which is raised from 0·082 per cent. to 0·125 per cent. during the earlier stages of the experiment but falls to 0·02-0·03 per cent. with the fall in body temperature. From these experiments the authors conclude that the relationship between vitamin B and appetite is the most important factor in producing the results observed, and that oxidation processes are normal in vitamin B deficiency: the majority of the symptoms are due simply to starvation, following the loss of appetite. That the oxidation processes of the body are normal in vitamin B deficiency, except when starvation enters into the picture, has also been shown by B. A. Lavrov and S. M. Matsko (*Jour. de Biol. et de Méd. Experiment.*, No. 9, p. 71; 1926).

Since pigeons have so often been used for experimental work on vitamin B, Drummond, working with S. K. Kon, has investigated the relationship of the symptoms of vitamin B deficiency to those of simple undernutrition in these birds also (*Biochem. Jour.*, vol. 21, p. 632; 1927). Each bird on the vitamin-deficient diet was controlled by another, which was only given to eat as much food as the former had consumed during the previous twenty-four hours, but was provided daily also with a liberal supply of vitamin B: in this way it was hoped to differentiate between the symptoms due to vitamin B deficiency and those due to simple undernutrition.

Of all the various symptoms observed by Drummond and Kon in these experiments only the loss of appetite and the nervous symptoms appeared to be specifically caused by absence of vitamin B from the diet. Nervous symptoms appeared in 79 per cent. of the birds within a month, and in 47 per cent. a temporary spontaneous improvement was noted (Kon, *ibid.* p. 834): in these experiments the birds were kept on a synthetic diet of the type used in experiments with rats: on a polished rice diet, 60 per cent. developed symptoms, which were speedily followed by death, no remissions being observed. The failure of appetite is associated with delay in the emptying of the crop: if forcibly fed, the crop still fails to empty normally, and the major portion of the food is vomited, so that the birds obtain no more nourishment than if left to feed themselves. The authors offer as explanation of the temporary improvement of the symptoms in so many birds on a synthetic diet, the suggestion that the convulsions in some way liberate vitamin B from the tissues and so make it available to subserve its function in nutrition.

The cause of the nervous symptoms is obscure: the organic lesion can only be slight, since injection of a preparation containing the vitamin will restore a pigeon to a normal condition in a few hours. The characteristic head retraction in this bird bears some resemblance to the forced movements or attitudes which can be obtained by stimulation of the labyrinth or its central connexions, but the nervous symptoms occur in birds in which the labyrinth has been destroyed (L. A. Tscherkes and T. M. Kuperman, *Jour. Biol. et Med. Exper.*, No. 8, p. 13; 1926). Nervous lesions demonstrable histologically have been described in both birds and rats. In the fowl, P. G. Culley (*Quart. Jour. Exp. Physiol.*, vol. 17, p. 65; 1927) has found that the myelin sheath of the affected nerves shows irregular swelling and fragmentation, but that the axis cylinder is not affected until polyneuritic symptoms appear: the changes resemble those occurring after section of a nerve, except that the alteration in the axis cylinder is considerably delayed. In the rat, H. H. Woollard (*Jour. Anat.*, vol. 61, p. 283; 1927) has only found lesions in the nerve-endings, both sensory and motor, of the voluntary muscles and in the intramuscular nerve fibres: they take the form of swelling of the nerve endings and fragmentation of the myelin in the sheaths of the nerve fibres, but the nerve axons remain intact. Similar, but less generalised, lesions occur in animals starved for a few days, and they can still be found even if vitamin B has been administered during the period of starvation. No lesions were observed in any other parts of the nervous system, central or peripheral.

It appears, then, that the lesions observed cannot be directly the cause of the symptoms, since they are too extensive to be abolished in a few hours, but they probably lead to a change in the axis cylinders or nerve-endings not demonstrable by present histological technique, which can be prevented or cured by administering the vitamin: the position is, however, rendered obscure by the fact that similar gross lesions are observed in starvation, and it is possible that starvation rather than vitamin B deficiency *per se* is the primary cause of both lesions and symptoms, the appearance of the latter, however, depending on the length of time the animal can live on the deficient diet, as compared with the short duration of a complete starvation experiment.

The actual amount of the vitamin required in the diet depends both on the diet and on the physiological condition of the animal. Thus Gladys A. Hartwell has shown that the rat requires about four times more vitamin B in the diet when rearing young than for growth or reproduction (*Biochem. Jour.*, vol. 19, p. 1074; 1925), whilst Drummond and Plimmer and their co-workers have demonstrated a relationship between the amounts of some of the other constituents of the diet and the vitamin B, which must be adhered to if optimal conditions for growth and maintenance are to be obtained (J. C. Drummond with Vera Reader, *ibid.*, vol. 20, p. 1256; 1926: and with A. Hassan, vol. 21, p. 653; 1927: R. H. A. Plimmer, J. L. Rosedale, and W. H. Raymond, *ibid.*, vol. 21, p. 913).

It is well known that the onset of symptoms of polyneuritis in birds is earlier in those which consume more of the deficient diet, and in those kept on a diet consisting chiefly of corbohydrates, whilst the onset is latest when the chief constituent of the diet is fat. Using young chicks or ducks, and, in the case of the carbohydrate diets, pigeons and rats also, limmer and his associates have succeeded in demonrating a definite dependence of the vitamin B connt of the diet upon the amounts of the other three ief constituents present if maximal growth and ealth are to be obtained.

The plan of the experiments was to feed diets conting chiefly of protein, fat, or carbohydrate, together th salts and vitamins, and vary the relationship of vitamin B to the main dietary constituent until isfactory growth was obtained. The authors found t the ratio of dried yeast (as source of vitamin B) the total calories in the diet was a constant and varied from 1 : 40 in the case of the chick, for a predominantly fat or carbohydrate diet, to 1 : 80 in the pigeon and 1 : 160 in the rat. Young animals require more than adults. The authors advance the suggestion that vitamin B is a constituent of the nucleus of every cell (perhaps a pyrimidine or purine compound), and thus the amount required depends on the total metabolism of the animal.

Drummond, working with rats, has observed that the ratio between the protein content and the yeast extract of the diet must be in the neighbourhood of 5, if growth is to be normal: with ratios of 18, growth was poor. He was unable to trace any relationship between the calories or the carbohydrate of the diet and the vitamin B content, thus failing to confirm the conclusions to which Plimmer was led by his experiments. The diet used by the latter for his rats contained no less than 94 per cent. of white flour, 5 per cent. fishmeal and 1 per cent. cod-liver oil completing it together with varying amounts of yeast extract: in none of Drummond's diets was the starch, as source of carbohydrate, higher than 70 per cent., nor did the protein content, in these experiments, caseinogen, fall below 20 per cent.: cod-liver oil, salts, lemon juice were also added, together with varying amounts of yeast extract, whilst fat sometimes replaced starch to increase the caloric value of the ration: in these differences between the diets used may lie the explanation of the somewhat different conclusions of the two observers.

That vitamin B really consists of two separate substances has been suggested by a number of different observations, but only recently has this differentiation become an established fact. Harriette Chick and Margaret H. Roscoe (*Biochem. Jour.*, vol. 21, p. 698; 1927) describe the two factors as the 'antineuritic,' which prevents polyneuritis in birds and paralysis in rats, and the 'pellagra-preventive' (of Goldberger), which prevents pellagra in rats, both together forming the water soluble vitamin B and both being necessary for normal growth. In a review of the literature, the authors point out that the two factors show certain differences in distribution; *e.g.* the antineuritic predominates in wheat embryo, but the antipellagrous in milk, meat, green leaves, etc., and that the antineuritic is more easily destroyed by a temperature of 120° C. and is more soluble in certain organic solvents such as alcohol, acetone, or benzene. In their experiments, the authors have confirmed the work of Goldberger and his associates on this subject.

The experiments were carried out on rats maintained on a synthetic diet: various preparations of yeast and wheat embryo were used as sources of the vitamins. On the basal diet alone, the animals died in a few weeks, usually without developing any symptoms: administration of dried yeast then permitted of growth and prevented death: if the yeast were first autoclaved, the animals died just as on the basal diet alone: if an alcoholic extract of yeast were given, the animals lived for some time, but without growth, and ultimately developed the symptoms of pellagra, characterised by ophthalmia, loss of fur, and dermatitis of the ears, paws, and neck. This condition could be cured, and at the same time growth restored, by the administration of autoclaved yeast. It is thus clear that the alcoholic extract of yeast contains the antineuritic factor, and the autoclaved yeast only the antipellagrous: growth occurs only when both are present together. The authors also confirmed the observation that wheat embryo contains mainly the antineuritic factor.

Hassan and Drummond have obtained similar results in their experiments (*loc. cit.*); thus rats kept on a high protein, low yeast, diet failed to grow satisfactorily until additional autoclaved yeast was added to the diet: but if only autoclaved yeast was used, growth again failed to occur, but could be produced by the administration of small amounts of an alcoholic extract of yeast. The balancing of the protein in the diet appeared to be the function of the thermostable factor.

With this differentiation of vitamin B into two parts, greater knowledge of the chemistry of this vitamin should be soon obtained. Some light is thrown on the chemical nature and properties of the antineuritic factor by recent work by H. W. Kinnersley and R. A. Peters (*Biochem. Jour.*, vol. 21, p. 777; 1927, and by U. Suzuki and Y. Sahashi in Japan (*Scientific Papers, Inst. Physic. and Chem. Res.*, vol. 4, p. 295; 1926, and vol. 5, p. 191; 1927). Kinnersley and Peters have purified their yeast extract ('torulin') until only 0·15-0·3 mgm. per day is necessary to cure polyneuritis in pigeons.

The methods of extraction and purification used are briefly as follows: Yeast autolysed for three days at room temperature is extracted twice with boiling water: the combined filtrates are treated with neutral lead acetate, the precipitate removed and the filtrate treated with baryta. On filtration, a crystal clear yellow fluid is obtained containing 6000 doses of torulin from 14 lb. yeast. The barium is removed as sulphate and the filtrate treated with acid mercuric sulphate: after removal of the precipitate the reaction is adjusted to *p*H 7·0 and purified 'Norite' charcoal added. The charcoal adsorbs the torulin, which can be removed from it by extraction with hot 0·1 *N* hydrochloric acid, or with acid alcohol. About 60 per cent. of the torulin contained in the baryta filtrate is recovered. For prolonged feeding experiments, it is advisable to omit the mercuric sulphate stage: the solution can be cleared by 'Norite' charcoal, provided the *p*H is at 2·5, since at this reaction the torulin is not adsorbed, but remains in solution. Further purification may be affected by a prolonged alcohol fractionation, following removal of any traces of metals with hydrogen sulphide.

The purified material contains 15-25 per cent. nitrogen: it is soluble in absolute ethyl alcohol, but is not adsorbed on 'Norite' charcoal, like the impurer preparations, so that adsorption must be a property conferred on the torulin by some accompanying impurity. The Pauly reaction becomes less intense as the material is purified. The authors identify torulin with the thermolabile growth factor and consider that it is probably the same as the anti-beriberi vitamin. In view of the work previously discussed, the opinion that the antineuritic, antiberiberi, and thermolabile growth factors are the same substance appears to be justified at present, although future work may show the necessity of differentiating between them.

The Japanese workers have obtained a substance, which they call 'Oryzanin,' from rice-bran or yeast, which cures polyneuritis in pigeons in doses of about 5 mgm. The material was obtained from an alcoholic solution of rice-bran, by precipitating impurities with lead acetate and the active material with phosphotungstic acid, followed by silver nitrate. When boiled with dilute acids, the substance was split into glucose, choline, nicotinic and 2·6-dioxychinolin carboxylic acids. The latter has been found to have a stimulating effect upon the growth of yeast, whilst a closely related compound, 2·6-dioxychinolin hydrochloride, in doses of about 7·5 mgm. daily, injected intramuscularly, cures the polyneuritis of pigeons, but has no influence on their weight. The authors consider that these compounds are closely related to the active principles contained in rice-bran: caution must be exercised, however, in accepting this conclusion, since the substances isolated might be contaminated with minute traces of a very highly active compound, in the same way as the activity of irradiated cholesterol has been shown to be due to contamination with small amounts of ergosterol, the latter only being converted into vitamin D on irradiation.

The work reviewed above offers hope that the designation 'vitamin B' will soon have to be discarded in favour of the proper names of well-defined chemical compounds, and that their isolation will be followed by their synthesis in the laboratory.

Biology of the Gulf of Mannar.

THE recent *Bulletin* of the Madras Government Museum, edited by the Superintendent (The Littoral Fauna of Krusadai Island in the Gulf of Mannar. New Series. Natural History Section, vol. 1, No. 1. 1927. P. 196. Madras: Government Press. 8 rupees), is the first issue of a new series of Madras Government publications on the natural history of animals and plants, as distinct from a general section dealing with archæology, anthropology, and allied subjects. The treatment of the subject in this number is one intermediate between a textbook and a specialist's monograph. Descriptions of many common species of invertebrate animals found on Krusadai Island in the Gulf of Mannar and in neighbouring localities are given. The classification followed is either that of the "Oxford Zoology" or of the "Cambridge Natural History." A new genus is described, Pseudocaprellina, in the suborder Caprellidea. There are two appendices, the first on the vertebrate fauna and the second on the flora of the island.

The various authors, among whom Dr. F. H. Gravely and Dr. B. Sundara Raj are prominent, have adopted a useful system of describing the common species, of which no up-to-date account exists within the reach of the Indian student. They have illustrated their papers well and given good lists of literature under each group. This publication will be valuable to students not only as a preliminary guide to the fauna and flora of the Island, but also as a stimulus to collecting and to subsequent research in the biological world of India.

The southern side and the eastern part of the northern side of the Krusadai Island are entirely sandy; the western part of the northern shore is very muddy and fringed with mangroves. A salt marsh, bounded on its southern and eastern sides by high sand dunes, extends from the northern shore across the whole width of the island, a little to the east of the middle. Tolerably fresh water can be obtained from shallow pits dug in the sand. Swarms of anopheline larvæ have been found, but no mosquitoes have been seen in September or in April-May.

From this island there is an easy approach to collecting grounds in Shingle Island, Kutikāl Point on Rāmēswaram Island, Pāmban Channel, and Rāmēswaram. Shingle Island gives ample opportunities for observing corals in their natural surroundings; Kutikāl Point is a good place for collecting medusæ and other pelagic forms; the Pāmban Channel is extraordinarily rich in hydroids, polyzoa, ascidians; and Rāmēswaram is interesting, as its fauna is very different from anything yet found in the immediate neighbourhood. With such surroundings and the prospects of the establishment of a Marine Biological Station in Krusadai Island, there is every hope that much information of interest on tropical marine life will be forthcoming in the near future.

University and Educational Intelligence.

EDINBURGH.—Dr. A. E. Cameron, professor of zoology and entomology in the University of Saskatchewan, has been appointed lecturer in medical entomology in the Department of Zoology as from Oct. 1 next.

LIVERPOOL.—The University will celebrate the twenty-fifth anniversary of its Charter on May 10 and 11, when honorary degrees, including the following, will be conferred:—D.Litt.: Lord Crawford and Balcarres, Chancellor of the University of Manchester, for eminent services to art, literature, and education; Prof. T. Percy Nunn, professor of education in the University of London and principal of the London Day Training College, for distinguished contributions to philosophy and education. D.Sc.: Prof. J. E. Littlewood, Rouse Ball professor of mathematics in the University of Cambridge, for distinguished contributions to mathematical science; Prof. Robert Robinson, professor of organic chemistry in the University of Manchester, for eminence as an organic chemist. LL.D.: Mr. William M. Childs, Vice-Chancellor of the University of Reading, for eminent services to university education in England; the Right Hon. H. A. L. Fisher, Warden of New College, Oxford, for his distinction in scholarship and his services to education in England; Prof. J. W. Gregory, professor of geology in the University of Glasgow, for distinguished services to geology, geography, and exploration. D.Eng.: Prof. J. A. Fleming, emeritus professor of electrical engineering at University College, London, for distinguished services in the advance and application of electrical science.

LONDON.—As from the beginning of the session 1928–29, in place of the existing Department of Philosophy and Psychology at University College, a Department of Philosophy and a Department of Psychology have been instituted. Prof. C. E. Spearman, now Grote professor of philosophy of mind and logic, will be head of the Department of Psychology, his title being changed to professor of psychology in the University of London.

The title of assistant professor of mechanical engineering at University College has been conferred on Mr. B. J. Lloyd-Evans.

The following doctorates have been conferred: D.Sc. in Anatomy on Mr. W. E. Le Gros Clark, University professor of anatomy at St. Bartholomew's Hospital Medical College, for a thesis entitled "On the Anatomy of the Pentailed Treeshrew (*Ptilocercus Lowii*)"; D.Sc. in Biochemistry on Mr. F. W. Fox (Imperial College—Royal College of Science), for a thesis entitled "Some Studies in Sterol Metabolism"; D.Sc. in Chemistry on Mr. R. W. E. B. Harman (University College), for a thesis entitled "Aqueous Solutions of Sodium Silicates"; D.Sc. in Mathematics on Mr. R. G. Cooke (University and East London Colleges), for a thesis entitled (1) "On the Theory of Schlomilch Series," (2) "Gibbs's Phenomenon in Fourier-Bessel Series and Integrals," (3) "The Inversion Formulæ of Hardy and Titchmarsh"; D.Sc. in Statistics on Mr. John Wishart (University College), for a thesis entitled "1. On the Approximate Quadrature of Certain Skew Curves, with an Account of the Researches of Thomas Bayes. 2. The Generalised Product Moment Distribution in Samples from a Normal Multivariate Population."

The Petrie Medal for distinguished work in archæology has been awarded to Sir Aurel Stein.

OXFORD.—The outgoing Senior Proctor, Mr. E. Ll. Woodward, of All Souls', in the customary oration delivered on the expiry of his year of office, took occasion to remark on the scanty attendance at "the very centre of our self-governing society, the Congregation of the University." The younger masters, as he truly said, are rare visitors to this assembly. A remedy might be found if a time were allowed for questions. Speaking of the spaces in the Parks taken up by the rightful claims of the new sciences, he suggested that by way of compensation a new garden and plantations might be laid out in the University's land on the other side of the Cherwell.

ST. ANDREWS.—Dr. J. C. Earl has been appointed to the chair of organic chemistry, pure and applied, in the University of Sydney, in succession to Prof. Kenner. Dr. Earl, who has lectured on organic chemistry in the University since 1922, has conducted investigations on fibrous materials, essential oils, and other products of Australian origin.

AN interesting exhibition was held at the Battersea Polytechnic on Friday and Saturday, Mar. 23 and 24, when the institutes concerned with continued education in the Battersea and Wandsworth areas held a combined exhibition, showing the work done by their students and the facilities offered for such work. The exhibition was opened by Lord Riddell, and the chair was taken by Mr. Alexander Glegg, vice-chairman of the governing body of the Polytechnic. In a short address, Lord Riddell referred to the increasing importance of technical education as related to industry, and the vital need for the nation as a whole to realise that success and happiness can be achieved only by hard and regular work. After the inaugural meeting, the guests spent a considerable time in going round the various exhibits, and were not slow in expressing their astonishment at the nature and scope of the instruction obtainable in the various institutes of the district. The whole of the Polytechnic was open for inspection, and the work shown included engineering, woodwork, building construction, chemistry, physics, hygiene and physiology, art and crafts, domestic science, elocution and dramatics, music, physical training, and many other branches of education. A pleasing phase of the exhibition was the keen interest shown by the many hundreds of young people of both sexes who attended.

INDUSTRIAL Education in 1924–1926 is dealt with in a *Bulletin*, No. 29 of 1927, of the United States Bureau of Education, which will be read with interest in Great Britain in connexion with the Emmott Committee's report, recently published, on the relationships of technical education to other forms of education and to industry. Among other outstanding features of education in America are mentioned: a growing tendency to discriminate more effectively between manual arts courses and vocational courses, with a growing recognition of the former as a part of general education; marked increase in the number of schools offering some form of apprenticeship work, occupational information courses and systematic vocational guidance; increase in the use of the kinematograph and other visual aids in industrial schools; development of itinerant teachers' courses in manual arts and agricultural engineering in rural districts; rapid increase of a new type of organisation, known as the general shop, for teaching elementary work in a number of more or less related activities, such as wood-work, electrical plant, automobile repairing, forging, machine shop, and mechanical drawing; continued change in the emphasis of instruction in manual arts courses from skill in the use of tools and machinery to general elementary, fundamental, manipulative abilities.

Calendar of Customs and Festivals.

April 1.

All Fools' Day.—The custom of sending anyone on a fruitless errand and consequently exposing them to ridicule, sometimes erroneously stated to be confined to England, though it occurs also in Continental countries, especially in France, Germany, and Sweden, has been variously explained as a survival of Roman festivals on which special licence prevailed, as a memory of the mockery of Christ by the Jews, or even as a memorial of the bootless errand of the first dove sent from the Ark by Noah. An etymology of 1656 explains the French phrase for April Fool—*poisson d'Avril*—as a corruption of Passion, connecting it with the manner in which Christ was sent from authority to authority before the crucifixion. The custom may be connected with the festival of the vernal equinox in the Celtic year, and it has been compared to the festival of that date in India which is traced to the ancient Persian calendar.

Palm Sunday.—The carrying of boughs in procession in church in commemoration of our Lord's entry into Jerusalem was one of the ceremonies specially exempt from the liturgical reforms of Henry VIII., although it was intermitted under Edward VI., and always abhorred by the stricter Protestants on account of its 'superstitious' character. This was due not only to the practice of hallowing the palms, but also to a number of beliefs and practices, many more probably popular than ecclesiastical in origin. In Roman Catholic countries and in England before the Reformation, box was the usual substitute for the palm. In the Domesday survey, a supply of box twigs on Palm Sunday was a condition of tenure of one of the Shropshire farms. Later, willow branches with their catkins, which are usually in flower, have generally been used, and the willow in bud is still called 'palm' in popular diction.

The palm used on Palm Sunday had special virtues. Barnabe Googe, in describing the procession of the wooden figure on a wooden ass, speaks of the people throwing branches before and on both the figure and the ass on its way to, and in, the church, which they then snatched up because of their special virtue. The use of the ashes of the previous year's palm on Ash Wednesday has already been mentioned. The custom of roasting eggs in the palm ashes was condemned in the Protestant Church. It was a belief of more than popular currency that the ashes were a sovereign remedy for disease, especially ague and worms. Roman Catholics carried small crosses made of palm in their purses, and at Little Colan, Cornwall, on Palm Sunday crosses of palm were thrown into Lady Nant's well and an offering made to the priest. If the crosses sank it betokened the death of the inquirer before the year was out.

Among the English peasantry, Palm Sunday was made an occasion for rejoicing, not only in the cutting and bringing in of the palms during the week before the actual day, but also on the day itself. At Kimpton in Hertfordshire it was an ancient custom to eat figs on this day, which was known as Fig Sunday, and to keep wassail, and there are several records beside that of Barnabe Googe, that after the Church procession boys sang and collected money, bread, and eggs from the people in the town or neighbourhood. Its possible connexion or confusion with an agricultural festival is shown by the fact that Mothering Sunday in Wales was celebrated on Palm Sunday.

April 5.

Maundy Thursday.—The day for the distribution of royal alms at Westminster, which in earlier days took the form not only of a dole but also of the washing of the feet of a number of poor persons by the reigning monarch, and sometimes of poor women also by his consort. In number originally 13, they were afterwards made to correspond with the years of the king's reign or of his life, as is first recorded of King John. In the earliest records of the custom, it was performed by the head of a monastery, the number of people equalling the number of monks. It is not confined to England, but is a custom of the Roman Catholic and the Greek Church, the ceremony being performed by the Pope and the reigning monarchs of the respective countries.

Shere Thursday, an alternative name, probably refers to its character as one of the days of special solemnity in Holy Week, Shere being a mis-spelling of *Chare*, from Old German *Char*, although there is an explanation of some antiquity that on this day the hair and beard were cut to mark the end of Lent and as a preparation for the Easter festival.

In the Highlands of Scotland, if the stock of seaweed used as manure obtained by this day was still inadequate, a pot of porridge prepared with butter and other rich ingredients was taken to the shore and a portion poured into the sea from each headland with incantations.

April 6.

Good Friday, or God's Friday.—Certain special observances were enjoined upon the king as head of the State. He crept to the cross, which was laid upon a carpet, and kissed it. It was also the custom for him on this day to hallow a number of the rings called 'cramp rings'—a remedy for fits.

Cakes or small loaves of bread baked on Good Friday morning had certain special virtues. They were not intended to be eaten, but were put by until the next year. Fragments grated into water were sovereign remedies for certain ailments. The custom of marking this bread with a cross has been derived from the custom of the Greeks and Romans of marking their bread with crosses and intersecting lines. In the north of England a pudding containing leaves of the passion dock (*Polygonum bistorta*) was an indispensable dish.

In the Isle of Man and in the Highlands there was a special taboo on the use of iron on this day. In the Isle of Man no iron must be put in the fire; in the latter locality no iron was to enter the ground, and if a burial had to take place on this day, the grave was opened the day before and the earth replaced over the corpse with a wooden shovel.

According to an observer in about the year 1810, the sailors of South African and Portuguese ships in the London docks hanged a clothed wooden figure of Judas Iscariot to the rigging. On their return from church they lowered it to the deck, and dipped it in the dock three times. It was then beaten by all members of the crew until no clothes remained on its back.

April 7.

Easter Eve.—On this day the paschal taper was lighted with flint and steel. In various parts of England, boys played games with hard-boiled eggs as balls and marched in procession with torches. In Ireland the day was made an occasion for feasting, and at 12 o'clock at night Lent was driven out with clapping of hands and shouts. Before dawn, everyone went out to see the sun dance in honour of the Resurrection. All clothes should be new for Easter, to ensure good luck

Societies and Academies.

LONDON.

Geological Society, Mar. 7.—**Hilda K. Cargill, L. Hawkes**, and **Julia A. Ledeboer**: The major intrusions of south-east Iceland. The main plutonic intrusions into the Tertiary plateau-basalts of Iceland were discovered some forty-five years ago in the south-east of the island, but little is known of their field-relations or petrology; the present paper summarises the results obtained on summer visits to the more accessible localities. The outcrops are scattered; the largest one (the Slaufrudal Stock) is elongate in plan, and its area covers 1¼ × 4¼ miles. The relationship of intrusives to country-rocks is a discordant one, the intrusions being stocks with steep-sided walls and domed roofs (not laccoliths as formerly suggested). The elongation of the stocks is parallel to the strike of the regional dykes, and intrusion clearly took place under, and was facilitated by, crustal tension. All intrusions are multiple: the common association is that of gabbro and granophyre. A horizontal layered structure of granite and granophyre is visible in the Slaufrudal stock, which seems to have grown by the injection of successive sills with intermittent subsidence of the replaced block. The rocks belong to the calc-alkaline suite, and comprise in the order of differentiation gabbro-peridotite, gabbro, diorite, granodiorite, granophyre, granite, quartz-vein. Eight new analyses are given. The suite, with the addition of granodiorite, is similar to that of the main plutonic intrusions of Tertiary age in Scotland. Comment is made on the absence of alkaline types in a region of 'Atlantic' tectonics. In the whole Icelandic area intermediate rocks are relatively unimportant in bulk, the extrusives are dominantly basic, and the intrusives dominantly acid: this may be related to the superior mobility of the basic magma. The absence of a sedimentary 'floor' in Iceland is noted, and it is suggested that the preservation of the Iceland-Faeroes remnant is due to the intrusion beneath it of an acid magma.

Society of Public Analysts, Mar. 7.—**T. P. Hilditch**: Composition of the fatty acids present as glycerides in elasmobranch oils. Whereas normal marine animal oils contain 30-40 per cent. of acids of the C_{20} and C_{22} groups, the fatty acids of shark-liver oils are of relatively low unsaturation. Apparently there is some connexion between the deficiency of these highly unsaturated acids and the presence of large amounts of the highly unsaturated squalene.—**R. T. Thomson**: Behaviour of indicators in the titration of ammonia, sodium and calcium phosphates, the methylamines, puridine bases, and boric acid. In commercial analysis, for ammonia and the methylamines methyl orange is the most satisfactory, and Congo Red for pyridine bases. Methyl orange is also to be preferred as an indicator for boric acid in quantities not exceeding 0·2 gm.—**H. R. Jensen**: Cacao tannin. As tannin is probably a principal cause of astringency in chocolate, the cinchonine nethod has been applied to the determination of annin in cacao. The cinchonine tannate precipitate vas found to contain 4·4 per cent. of nitrogen, hich is similar to the 4·3 per cent. found in the hop d tea tannin compounds. The water-soluble tannin ntent of eleven samples of fully roasted cacao nibs nged from 5·2 to 6·3 per cent.

Royal Meteorological Society, Mar. 21.—**H. W. wton**: The sun's cycle of activity (Symons norial Lecture). The cycle of activity through ch the sun passes in a period of about 11 years is vn by various solar phenomena. There is the well-known variation in the number of sunspots and in the concomitant phenomena of bright calcium and hydrogen flocculi at higher levels. Above these is the region of prominences and dark hydrogen markings which show only a partial relation to the spot zones. The extended and outermost envelope of the sun—the corona—also undergoes a cyclical change. The cause of this 11-year period, though seemingly within the sun, is not known, and phase and amplitude of a cycle ahead cannot be predicted with accuracy. Sunspots are probably vortical in origin and are the centres of strong magnetic fields, the polarities of which, when similar spots are compared, have been found to be opposite in successive 11-year cycles. A theory dealing with the sun's general circulation and that of spots in particular has been advanced by V. Bjerknes. Measures of the solar-constant and of the sun's ultra-violet radiation indicate a change with the solar cycle. A similar variation in the reception of radio signals is also suspected. The occurrence of terrestrial magnetic storms and the corresponding state of the sun is briefly considered.

CAMBRIDGE.

Philosophical Society, Feb. 27.—**J. A. Gaunt**: A theory of Hartree's atomic fields. The equations used by Dr. Hartree in calculating atomic fields are compared by means of perturbation theory with the exact equation for an atom with many electrons. Many of the correction terms cancel out.—**F. Hurn Constable**: (1) On the present position of the theory of centres of activity in heterogeneous catalysis. A critical discussion, with evidence from the oxidation of active centres on iron, leads to the conclusion that the energy store in the active centres is not greatly in excess of that possessed by the regular arrangement of atoms in the surface. The theory seems adequate as so far developed to explain the facts of catalysis, though the quantitative development is somewhat tentative. (2) A method of generalising the law of mass action for heterogeneous surface reactions. To the conditions of reaction in homogeneous systems is added yet another condition, the adsorption of the reactants on the centres of activity of the surface. The surface is treated as if it were homogeneous, reaction taking place as if only those centres on which the heat of activation is smallest, were responsible for chemical change. The general equation is worked out in terms of the rate of bombardment and the mean lives of the molecules on the surface. It is incidentally shown that the same areas associated with the forward reaction must inevitably catalyse the backward reaction. The general solution is impracticable, so the special cases of irreversible synthesis and decomposition are considered.—**A. F. Crossley**: Operational solution of some problems in viscous fluid motion. The solutions are given of some two-dimensional problems: (i) on the motion which arises when a lamina of unlimited extent moves in its own plane in a viscous fluid, either infinite or confined between parallel plane boundaries; (ii) on the motion of a viscous fluid contained in a circular cylinder rotating about its axis.—**R. W. Ditchburn**: The photo-electric threshold and the heat of dissociation of the potassium molecule. The energy of dissociation of the potassium molecule is considered to be 0·50 ± 0·01 volts. The wave-length of the photo-electric threshold is 2555 A. ± 25 A. The mechanism of the photo-ionisation process is discussed in connexion with the recent work of Franck and his colleagues.

DUBLIN.

Royal Dublin Society, Feb. 21.—**Rev. H. C. Browne**: Stereoscopic notes. The utility of stereoscopic photography is generally reduced by the lack of uniformity of commercial apparatus. If full advantage is to be taken of stereoscopic principles, the stereoscope used must be designed to suit the camera. The adoption of definite, recognised standards is therefore desirable.—**J. H. J. Poole**: The measurement of the current flowing through a photo-electric cell by means of a neon lamp (*v.* NATURE, Feb. 25, p. 281).

Royal Irish Academy, Feb. 27.—**S. Young**: The boiling points of the normal paraffins at different pressures. The boiling points of the normal paraffins from methane to octane have been determined by various observers over a wide range of pressure, generally up to the critical point, and from nonane to nonadecane at a few pressures up to 760 mm.; and those of many of the higher homologues up to pentatriacosane, $C_{35}H_{72}$, at 15 mm. or a few pressures up to 25 or 30 mm. Three methods of calculation are employed: (1) The quite general formula $\Delta = A/T^B\sqrt{T}$ gives the approximate difference between the boiling points of any two consecutive homologues at any pressure. In this formula $\log A = 1{\cdot}92251 + 0{\cdot}026187 \log p + 0{\cdot}013987 (\log p)^2 + 0{\cdot}0013374 (\log p)^3$, and $B = 0{\cdot}01676 - 0{\cdot}000795 \log p$. (2) At any given pressure the boiling points of the normal paraffins may be calculated with fair accuracy by the formula $\log T = a + b \log n + c(\log n)^2 [+d(\log n)^3]$, where n is the number of carbon atoms in the molecule. The fourth constant d was only required at the three lowest pressures for the complete series from CH_4 to $C_{35}H_{72}$. (3) In this method each paraffin is compared with one of them, hexane, taken as a standard, at a series of pressures the same for both. The equation is of the form $1/T'_B = 1/T'_A[a + bT'_A + cT'^2_A]$, where A represents hexane and B the other paraffin.

EDINBURGH.

Royal Society, Feb. 20.—**E. B. Bailey**: Schist geology: Braemar, Glen Clunie, and Glen Shee. The Ben Eagach schist outcrop of Caenlochan Glen continues by Glen Shee to Glen Clunie. It there comes into contact with Blair Atholl limestones: (1) at Newbigging cottage owing to faulting, and (2) south-west of Morrone owing to sliding. Differences of rock character at Glens Clunie and Caenlochan are attributed to metamorphism. The structure of the district includes refolded recumbent folds and slides.—**H. H. Read**: The Highland schists of Middle Deeside and East Glen Muick. The Highland schists of these areas are divided into three groups which are correlated with the Pitlochry schists, Loch Tay limestone and Ben Lui schists of Perthshire. There is no discontinuity of outcrop between Perthshire and Aberdeenshire, and structures in the two areas are continued on the equivalent horizons. The Deeside schists lie, in a northerly pitching anticline, far above a culmination recognised in Tarfside.—**C. Norman Kemp**: The X-ray examination of coal sections. The X-ray examination of coal has hitherto for the most part been carried out on comparatively small and irregular pieces. The special methods of sawing developed at H.M. Fuel Research Station for the production of coal sections having smooth, flat, and parallel surfaces are described. The resulting slices, of a thickness of about 1 cm., and measuring sometimes 20 cm. by 15 cm., were subjected to radiographic examination. Comparisons within and between radiographs acquire a new degree of precision, and, in marked contrast with former results, the negatives are so sharp that moderate degrees of enlargement may be employed for the study of finer structural details.—**Edward Henderson**: An X-ray examination of saturated dicarboxylic acids and amides of the fatty acid series. Additional members of the series of normal saturated dicarboxylic acids have been investigated and the results are in agreement with the conclusions already arrived at (*J.C.S.*, **129**, 2633; 1926). A number of mono- and di-alkyl malonic acids have been studied. Successive reflection planes are separated by the length of one molecule. The series of fatty acid amides resembles closely the series of fatty acids.—**W. L. Ferrar**: Generalised derivatives and integrals. The various definitions of D^nf, n not a positive integer, are considered. Pincherle's operator is a representation of the analytic function given by Riemann's definition. Limiting processes applied to Δ^nf lead to Liouville's, and not Riemann's, definition.

LEEDS.

Philosophical and Literary Society, Feb. 21.—**C. A. Ford**: Discontinuous fluid motion past an elliptic barrier.—**R. Stoneley**: A Rayleigh wave problem. The propagation of waves of the Rayleigh type is examined for a compressible elastic solid of finite depth, with one surface fixed. The wave-velocity depends on the wave-length, and may have any value greater than that of a simple Rayleigh wave in th medium. The wave-velocity equation is also deduced as a limiting case of Rayleigh waves in a surface layer. —**H. Jones** and **R. Whiddington**: Note on the energy losses of electrons passing through hydrogen. A brief introductory account of experiments using a photographic method in which radiation quantum losses are observed using 100 volt electrons in hydrogen at low pressure. The view is taken that the hydrogen molecule and H_2 are mainly concerned.—**R. Whiddington**: Some experiments with electrons passing through fine slits. Certain highly complicated energy changes have been observed when electrons of about 100 volts energy are passed in a good vacuum through a fine slit. The apparent occurrence of energies in excess of the greatest expected are due probably to an inherent instrumental effect.—**S. R. Pike**: The physical conditions in new stars. The corrections required to reduce the visual to the bolometric magnitudes of stars have been calculated for surface temperatures between 20,000° A. and 120,000° A., and are applied to show that the increase in brightness of a nova cannot be due to temperature changes alone, but must involve a large increase in radius. For Nova Aquilæ the rate of expansion of the photosphere can be found approximately, and it exceeds the parabolic velocity. Consideration of the degree of ionisation of the resultant expanding shell of gas yields information about its density, and about the temperature of the central star at various times.—**E. C. Stoner**: On the distribution of electrons among atomic levels. A number of unjustifiable applications have been made of a scheme previously put forward for the distribution of electrons among atomic levels. The classification of electrons in n, k groups is discussed and the spectroscopic significance of X-ray levels is considered. Electrons cannot be subdivided into grouplets specified by n, k, j values appropriate for X-ray levels.—**E. Percival** and **H. Whitehead**: Observations on the ova and oviposition of some Ephemeroptera and Plecoptera. The ova and oviposition of seven species of Plecoptera and four species of Ephemeroptera are described. The eggs of Perlodes and Perla are modified for attachment to the substratum. Three groups of eggs are to be separated, (*a*) those carried by the female, before oviposition, in masses held by a water-soluble cement, (*b*) those eggs held together by a water absorbent cement which is not soluble, (*c*) those which are attached directly to the substratum by the female, ich creeps down into the water. An attempt is le to correlate the behaviour in water of some with that of sand grains.—**R. G. S. Hudson**: (1) Lower Carboniferous corals: *Cravenia rhytoides* *enia tela*, gen. et spp. n. Among the Rugose c the Lower Viséan of the Central Province, th various small cornute forms with a complex Cli llid central column and a simple Caninoid sept a. In development these forms show early speci ion in a particular structure which later becan e characteristic feature of the dominant Rugose rals of the Upper Viséan. (2) The Lower Carboniferous corals: development of *Lithostrotion cyathophylloides*, Vaughan. The structure of this species shows that it is not a Lithostrotion but a Cyathophyllid coral which has a Clisiophyllid trend, and in its late growth stages possesses a medial plate and arched tabellæ, thus approximating to the structure of Clisiophyllum.—**F. C. Stewart**: The maintenance of semi-permeability in the plant cell during leaching experiments. Leaching phenomena applied to living tissues do not afford a means of ascertaining the chemical nature of substances in the cell walls or limiting protoplasmic surface of plant cells. Protracted leaching experiments indicate that such treatment does not necessarily result in loss of semi-permeability. This is not in accordance with the view that leaching involves removal of those substances responsible for the permeability properties of living cells.

PARIS.

Academy of Sciences, Feb. 20.—**Gabriel Bertrand** and **L. Silberstein**: The proportions of barium contained in arable soil. The method of determining barium in soil is given in detail. The proportions found range from 0·008 per cent. to 0·17 per cent.—**Louis Roy**: The general equations of elastic surfaces.—**J. Le Bel**: A cyclic system connected with harmonic surfaces.—**B. Hostinsky**: Complement to the note on the probabilities relative to repeated transformations.—**R. Gosse**: The equations $s = qf(x,y,z,p)$.—**R. Wavre**: The permanent rotations of a heterogeneous fluid mass and geodesy.—**Seth B. Nicholson** and **Nicolas B. Perrakis**: The constitution of the solar atmosphere. It has been proved that a large number of known elements are absent from the solar atmosphere, and an attempt is made to see if these absences are accidental or depend on reasons connected with atomic structure. The solar atmosphere contains neither extremely stable elements, such as the rare gases, nor specially unstable elements, such as the radioactive bodies. The absences, apparent or real, occur periodically as the atomic number increases. The total, or almost total, absence of the heavy elements is difficult to explain.—**H. Deslandres**: Remarks on the preceding communication.—**Louis Kahn**: A conformal chart utilisable as an orthodromic chart for long routes.—**Winter**: Vibrating spaces.—**Mlle. Paule Collet** and **Francis Birch**: The magnetic moments of the cupric ion. The usual moment of the cupric ion is ten magnetons, but in one case nine magnetons were found.—**B. Cabrera**: Internuclear reactions.—**Henri Moureu**: The tautomerism of the α-diketones. Constitution of the two forms of methylbenzylglyoxal. One of the isomerides of methylbenzylglyoxal is a true α-diketone: the other has the keto-enolic form, $C_6H_5 . CH : C(OH) . CO . CH_3$.—**A. Demay**: The upper elements of the Cévenol tectonic complex, the Pilat and Laval strata, in the Pyfara face and in the Saint-Marcel synclinal.—**Conrad Kilian**: The presence of the Silurian to the east and south of Ahaggar.—**E. Bruet**: The conditions of formation and of conservation of the upper Pliocene of the Aujon valley.—**A. Guilliermond**: Remarks on the phylogeny of the Ascomycetes.—**Michel-Durand**: The physiological rôle of the pyrogallic tannins.—**Y. Volmar** and **A. Jermstad**: The essential oil of *Salvia Sclarea*. The results of a detailed physical and chemical examination of the essential oil of sage.—**D. Chouchak**: The presence of glycuronic acid in wines made from diseased or mouldy grapes. Wines produced from healthy grapes contain only traces of glycuronic acid: the determination of this acid in wine serves as a measure of the care taken with the grapes before fermentation.—**Georges Truffaut** and **N. Bezssonoff**: The usefulness of natural and soluble phosphates measured by a bacteriological method, and the effect on higher plants.—**Tsen-Cheng**: The histopathological modifications proved in the potato (*Solanum tuberosum*) attacked by degenerescence.—**A. Jullien**: The transformation of the blood cells of the cuttle fish (*Sepia off.*) in the course of aseptic inflammatory reactions.—**L. Mercier**: Contribution to the study of the loss of the power of flight in *Carnus hemapterus*.—**C. Dawydoff**: The embryology of the Protonemerta.—**Mme. Hélène Sorg-Matter**: The quantitative law of the minimum nitrogen consumption of the homœotherms: intraspecific validity.—**Angel Establier y Costa** and **Charles Kayser**: Analysis of the mechanism of hyperallantoinuria observed after the puncture of the fourth ventricle.—**Mme. M. Phisalix** and **F. Pasteur**: The action of ultra-violet light on the venom of *Vipera aspis*.—**Bordier**: The heat disengaged by diathermal d'Arsonvalisation with sponge electrodes: important disadvantages of these electrodes. Flexible metallic electrodes are preferable to sponges for making contact with the patient.—**Jean Saidman**: An automatic test for the sensibility of the skin.—**Barrien** and **Nemours-Auguste**: The technique and the results of the treatment of angina pectoris by radiotherapy. The treatment is absolutely without danger, provided care is taken to shield the thyroid gland. Out of seven cases there were five cures and one marked improvement.—**S. Metalnicov** and **V. Chorine**: Bacterial diseases in the larvæ of the maize moth, *Pyrausta nubilalis*.—**F. Picard**: The factors of geographical distribution of *Plasmodium vivax* and *Plasmodium præcox*.

VIENNA.

Academy of Sciences, Jan. 12.—**K. Beaucourt**: Condensation products of furfurol with acid amides.—**H. Mae**: Sudden transitions of temperature in the Baltic. North or south winds blowing along the length of the Gulf of Bothnia induce a vertical circulation, bringing cold bottom water to the surface.—**W. Blabensteiner**: The application of the ash picture for the determination of barks used in pharmacy.—**C. A. Bobies**: Quartz gravel in the marine sediments of the eastern Triesting.—**H. Pettersson**: The disintegration of carbon (3). Graphite was bombarded with α-particles of reduced range from polonium. These cease to liberate H-particles of observable range from carbon at a reduced range which lies between 1 and 2 cm. of air. Apparently a higher minimum energy of the α-particle is required for disintegrating carbon than for aluminium.—**K. Menger**: A theorem of topology. Notes on the theory of dimensions. (1) A proposition supplementing the definition of dimensions, (2) weak n-dimensional spaces, (3) n-dimensional growths.—**K. Czapla**: Ash pictures of technically useful barks. Barks useful in tanning can be recognised in test sections. The ash products were examined microscopically for crystals and use made of micro-chemical staining reagents.—**R. Wagner**: Anisophylly and partial inflorescences in *Salvia sclarea*.

Diary of Societies.

FRIDAY, March 30.

Institution of Naval Architects (at Royal Society of Arts), at 11 a.m.—Lt.-Col. V. C. Richmond: Some Modern Developments in Rigid Airship Construction.—G. S. Baker and J. L. Kent: Experiments on the Propulsion of a Single-Screw Ship Model.—At 3.—W. G. A. Perring. The Vortex Theory of Propellers and its Application to the Wake Conditions existing behind a Ship.—J. Tutin. Cavitation.—J. L. Taylor: Statistical Analysis of Voyage Abstracts.

Diesel Engine Users' Association (at Caxton Hall, Westminster), at 3.—D. Brownlie. Liquid Fuel from Coal

Institution of Locomotive Engineers (Manchester Centre) (at College of Technology, Manchester), at 7.—W. G. Smith: Some Features of the Mechanical and Electrical Equipment of the Port of Manchester.

Institution of Mechanical Engineers (Informal Meeting), at 7.—J. L. Hodgson and others. Discussion on The Problem of Utilising the Earth's Internal Heat.

Institution of Electrical Engineers (North-Eastern Students' Section) (at Lighting Service Bureau, Newcastle-upon-Tyne), at 7.15.—Annual General Meeting.

Junior Institution of Engineers (Informal Meeting), at 7.30.—C. F. Adams: Locomotive Maintenance.

Geologists' Association (at University College), at 7.30.—A. G. Davis: The Geology of the Clapham-Morden Railway Extension.—Miss Helen M. Muir-Wood: A New Brachiopod, *Discinisca ferronia*, from the Woolwich Beds.—E. M. Venables: The London Clay of Bognor.

Institute of Metals (Sheffield Local Section) (in Non-Ferrous Section, Applied Science Department, Sheffield University), at 7.30.—Dr. W. H Hatfield: Non-Ferrous Metals in relation to Ferrous Metallurgy.

Institution of Welding Engineers (at Caxton Hall, Westminster), at 7.30.—W. Steele: Bronze Welding.

Royal Institution of Great Britain, at 9.—Sir Ernest Rutherford: Radioactive Atoms and their Structure.

SATURDAY, March 31.

Royal Institution of Great Britain, at 3.—Sir Ernest Rutherford: The Transformation of Matter (IV.).

North of England Institute of Mining and Mechanical Engineers (Associates and Students' Section) (at Neville Hall, Newcastle-upon-Tyne), at 3.—B. H. Houle: The Installation of a Booster Fan.

MONDAY, April 2.

Victoria Institute (at Central Buildings, Westminster), at 4.30.—A. H. Forbes: Science in the Book of Ecclesiastes.

Royal Institution of Great Britain, at 5.—General Meeting.

Society of Engineers (at Geological Society), at 6.—R. W. A. Brewer. Air Cooled Radial Engines.

Institution of Automobile Engineers (Western Centre) (at Merchant Venturers' Technical College, Bristol), at 6.45.—J. N. Tait: Mixture Distribution in Multi-Cylinder Engines.

Royal Institute of British Architects, at 8.—Dr. H. Muthesius: Modern German Architecture.

Society of Chemical Industry (London Section) (at Chemical Society), at 8.—C. D. Adams: The English Beet Sugar Industry.

Surveyors' Institution (at Institution of Civil Engineers), at 8.—C. Dampier-Whetham. Agricultural Depression. its Causes and Possible Cures.

Royal Geographical Society (at Æolian Hall), at 8.30.—A. C. Hardy: The Work of the R R S. *Discovery* in the Falkland Islands Dependencies.

Society of Chemical Industry (Yorkshire Section) (at Leeds).—Annual General Meeting

TUESDAY, April 3.

Institution of Petroleum Technologists (at Royal Society of Arts), at 5.30.—Dr. A. Wade: The Oil Well and Later Developments at Hardstoft, Derbyshire.

Zoological Society of London, at 5.30.—Miss H. M. Brown: Exhibition of a Fluke (*Microcotyle alcedinae*) from the Gills of the Sea-Bream *Pagellus centrodontus*.—C. R. S. Pitman: (1) Notes on a Young Pangolin captured in January 1928; (2) Nkosi Island and its Sitatunga.—Dr. R. Gurney: Some Copepoda from Tanganyika collected by Mr. S. R. B. Pask.—Cambridge Suez Canal Expedition Reports:—(a) Prof. A. Palombi: Report of Turbellaria.—(b) Dr. A. Schellenberg: Report on the Amphipoda.—(c) F. A. Potts: Report on the Sedentary Polychaet

Institution of Civil Engineers, at 6.

Institution of Electrical Engineers (North Midland Centre) (a Hotel Metropole, Leeds), at 7.—Annual General Meeting.

Institution of Electrical Engineers (North-Western Centre) (a Engineers' Club, Manchester), at 7.—Annual General Meeting.—H B Poynder: Some Practical Considerations in the Design of Automatic Equipments for Heavy Traction Substations

Royal Photographic Society of Great Britain (Pictorial Group), at 7.—F. H. Evans. Westminster Abbey.

North-East Coast Institution of Engineers and Shipbuilders (Middlesbrough Branch) (at Cleveland Scientific and Technical Institution, Middlesbrough), at 7.30

Institution of Automobile Engineers (at Royal Society of Arts), at 7.45.—H. A Watson. The Electrical Characteristics of Spark Gap and Sparking Plug.

Royal Society of Medicine (Orthopædics Section), at 8.30.—Dr. C. Scudder: The Treatment of Recent Fractures by Operation.

Institution of Mechanical Engineers (Swansea Branch).—G. A. V. Russell: Reversing Blooming Mill Practice.

WEDNESDAY, April 4.

Geological Society of London, at 5.30.—Dr. G. W. Tyrrell The Analcite-Syenites and Associated Rocks of Ayrshire.—Dr J. Parkinson: The Pleistocene History of Western Buchivacoa (Venezuela).—A Tindall Hopwood: *Gyrinodon quassus*, a New Genus and Species of Toxodont from Western Buchivacoa (Venezuela).

Institution of Heating and Ventilating Engineers (at Gas Light and Coke Company, Watson House, Nine Elms, S.W.8), at 5.30.—J. G. Clark: Demonstrations of Method of Assessing the Radiant Efficiency of Gas Fires.—Methods of Examining Materials of all Kinds used in Gas Supply.—Testing of Gas Fittings for Soundness, Weight, and Quality.—The Testing of Wrought Iron Fittings for Soundness and Quality.—Methods of Ventilating Gas Appliances and of dealing with Adverse Winds.—Methods used for Instructing the Various Sections of the Staff of the Gas Sales Department.—The Use of Special Flues for Use with Gas Fires, etc.

Institution of Electrical Engineers (Wireless Section), at 6.—Prof. E. V. Appleton The Study of Signal Fading (The Work of the Radio Research Station at Peterborough)

Institution of Electrical Engineers (Tees-Side Sub-Centre) (at Cleveland Technical Institute, Middlesbrough), at 7.—D. S. Munro: Modern Electric Wiring, particularly as applied to Small Houses.

Society of Public Analysts and other Analytical Chemists (at Chemical Society), at 8.—J. Evans and T. E. Wallis: Coffee Parchment as an Adulterant of Bran and Sharps.—W. B. Adam: Determination of the Colour-producing Constituents of the Cacao Bean.—Dr. A. T. Etheridge: Determination of Vanadium in Steel.—S. G. Clarke: Colorimetric Determination of Antimony and its Separation from Tin.—Dr. A. Bird: Determination of Carbon Dioxide in Soils.

Royal Microscopical Society (Biological Section).

PUBLIC LECTURES.

MONDAY, April 2.

Gresham College, at 6.—G. P. Bailey: Modern Science and Daily Life: Summary and Some Outstanding Problems.

WEDNESDAY, April 4.

Medical School, Leeds, at 3.30.—Prof. G. E. Gask: Radium in th Treatment of Malignant Disease.

SATURDAY, APRIL 7, 1928.

Team Work.

WE welcome the appearance of another report of the Committee of the Privy Council for Scientific and Industrial Research, that for the year 1926–27, which will doubtless be received as an encouraging document in progressive political circles. For one thing, it represents the credit side of a balance sheet on the debit side of which there stands an item of some £450,000 of public money. In these days of necessary economy—and of even more necessary judgment in its incidence—a recital of the kind of goods that an outlay of half a million pounds will buy in the scientific market is an education by itself. For another, it gives some indication of the dimensions of the quarry in view. The Department performs the dual function of taking a part in assuring a supply of trained and experienced research workers, capable of applying themselves in their respective spheres to the solution of problems confronting British industry, and of instituting and co-ordinating the researches themselves for the benefit of the community.

It is, of course, unfashionable, almost indecent, to scoff at research in this twentieth century; the devotion and skill of the pioneers may have been taken for granted, but there have at least been enough of the more spectacular kind of successes in one branch or another not only to attract the popular attention, but also to awake a genuine concern for the vigorous prosecution of scientific researches with a view either to the amelioration of the conditions of life or to ultimate commercialisation. What is not so fully realised is the enormous amount of untiring, expensive, fundamental team work which must precede the successful completion or application of a discovery; the amount of minute and often apparently inconsequent detail which must be accumulated in order to fashion a single signpost of progress. The ten per cent. of inspiration in genius is readily acclaimed, but the ninety per cent. of perspiration is little appreciated, because undisclosed in the ordinary non-technical report. The labours of the less prominent members of the research community, moreover, although normally receiving due recognition at the hands of those who afterwards make use of them, are often more in the nature of fuel for the furnace than the heat itself.

Our contention, however, is not that the prizes are unequal, or even that the opportunities are equal, but merely that every honest contribution to the advance of our knowledge, provided it is accurately reported and adequately indexed, possesses a potential relative value which may far exceed its actual intrinsic value. In particular, the major problems of national concern lend themselves to organised team-work, and the Department of Scientific and Industrial Research, together with the laboratories and associations working under its ægis on co-operative lines, are effectively and unobtrusively 'delivering the goods.' The backing of the State puts selected investigators in the position of being able to spend both energy and money on an exploration of the foundations of industry to an extent which would be impossible were the rise of a superstructure the immediate and sole concern. Thus there is a solidity, as well as a catholicity, about the work done under such auspices.

Another important aspect of the Department's activities is the part which it takes, in conjunction with the universities, in making it possible for specially promising students to devote themselves to the preparation for and the practice of a career of research. It is recognised that such support is a means—possibly only a temporary means—and not an end; it is not of the nature and quality of a prize, but rather of an insurance. As we consider that, despite the enormous advances of the past decade, Great Britain has scarcely left the threshold of the scientific development of industry, we realise how necessary a policy this is. The premium costs but five per cent. of the expenditure.

Much thought has been devoted to the question of the propriety of giving or continuing maintenance grants to students. It is satisfactory to find that inquiry shows the number of cases in which the award proves unjustified to be negligible; it is equally satisfactory to find that, even in the chemical profession, where there is a superfluity of aspirants, 66 per cent. of the former recipients are now employed in research in industry, in Government laboratories, or in the universities. It seems clear that the policy of the Department in this respect, although it may require some modification from time to time to meet the changing aspect of industrial and scientific affairs, has proved both economic and fruitful; it is evident that some such opportunity for training in the application of academic knowledge and of academic methods in the industrial arena, whether it be carried out under public or private direction, is an essential link in the chain.

Probably the weakest link is here, in the use which we make of scientific knowledge, scientific potentialities, and particularly of scientific method. We hear much of the lack of appreciation of industrial conditions evidenced by young university graduates, of their unpractical equipment and the like, but too little of the new directions in which the methodical, critical, analytical, and finally synthetic processes of thought and of action in which they have been trained can be brought to bear on the difficulties and the opportunities of the work-a-day world. This application is by no means an automatic process, and the Advisory Council emphasises its significance. Britain, it declares, is not behind others in purely scientific work; what she lacks is the application of scientific discoveries, and above all of scientific method, to industry. It is to such organisations as the research associations that we look specially to hold fast to both partners, and to make their co-operation both possible and profitable. "New industries," says the Report, "may spring up from individual discoveries and by individual effort, but as a new industry grows or merges into a staple industry it will depend more and more on co-operative effort for its health and progress. In this co-operative effort, which is needed to preserve and develop our great industries, the scientific man must take his share; he must be concerned with the necessity for improvement in detail no less than with more spectacular endeavours to strike out into new paths."

These considerations bring us fairly and squarely in view of the main business of the Department, namely, to accumulate, either by assembly or direct inquiry, scientific results of a character suitable for immediate application in support of industry, and to lay sure foundations for its further development. No one who knows anything about the subject nowadays disputes the contention that organised research is, broadly speaking, a paying proposition, although there may be a considerable lag between the expenditure and its profitable return. Individual researches may, and often do, lead to no practical advantage, whereas others realise a handsome profit out of all proportion to the cost; in consequence, only the larger industrial concerns can support capital charges adequate to ensure a profitable proportion of commercially successful results of major dimensions, whilst the smallest firms can share in the rewards of such investigation by supporting the work on a co-operative basis. There are twenty-four such associations, and the majority are in receipt of financial assistance from the Department. It is surprising, however, to find that the Research Association of British Motor and Allied Manufacturers receives so little support from the now prosperous industry — substantially less than an amount represented by sixpence per motor vehicle produced annually by the industry—as to render it ineligible for a grant from public moneys. We cannot claim to know all that is necessary for maintaining a world-wide supremacy in this direction, so that it would appear that we are more afraid of our competitors at home than abroad. If this is in fact the case, or if the attitude of the industry is determined by some other reason, our hopes for the future must rest entirely on the experimental work which individual firms are able to carry out. This work, of course, is a very long way from being inconsiderable.

The existence of a National Research Council in Canada, a Commonwealth Council for Scientific and Industrial Research in Australia, a Department of Scientific and Industrial Research in New Zealand, and technical boards in South Africa and India, is one of the most encouraging premonitions of a reawakening Empire prosperity. Team work on a national scale can scarcely fail to be as productive of results as team work on an individual basis. The Empire Marketing Board rightly advises us to spend our money in such a way as to keep as much as possible "in the family"; the duty is also laid upon us as members of that family to advise one another concerning the use of our diverse opportunities in the common weal, and to explore our heritage in concert with a view to the efficient exploitation of the family estates. In such a case not only wealth, but also better health and greater happiness are unlikely to be denied us.

The Electronic Theory of Valency.

The Electronic Theory of Valency. By Dr. Nevil Vincent Sidgwick. Pp. xii + 310. (Oxford: Clarendon Press; London: Oxford University Press, 1927.) 15*s.* net.

WHEN the electronic structure of matter had been demonstrated, and the electrons in the atom had been not only counted but also classified by means of spectroscopic data, it was inevitable that attempts should be made to correlate the new data in reference to atomic structure with the commonplace facts of chemistry. In the case of metallic salts, which have been shown by X-ray analysis to be ionised completely even in the solid state, the application of physical data has been comparatively easy, since the attractive forces in an aggregate of ions can be calculated, and the principal unknown quantity is the compressibility or deformability of the ion. This can be expressed as a repulsion varying inversely as the nth power of the distance, the value of n being about 9 for crystals of the sodium chloride type, in which each ion is surrounded by *six* atoms of opposite sign; in crystals of the cæsium chloride type, however, where the envelope includes *eight* ions of opposite sign, the value of n is greater, whilst the *four* ion envelopes of the zinc sulphide type require a smaller index. These simple considerations are complicated by the mutual polarisation of the ions, which introduces another independent constant in the calculations; but, by assigning an arbitrary value to this constant, it has been possible in a considerable number of cases to calculate, by means of data derived from independent sources, the physico-chemical properties (*e.g.* the heat of sublimation, and the molecular volume) of crystalline compounds of this type.

On the other hand, when atoms are united into molecules by means of 'bonds,' the problem at once passes beyond the present scope of physical calculations, since the nature of these bonds cannot yet be defined in terms of known physical quantities. An interesting situation has thus been created. On one hand, physicists have yielded only too readily to the temptation to ignore these inconvenient linkages, and have assigned ionic structures to compounds in which the chemical evidence points clearly to the existence of molecules, held together by real bonds. Thus, since water at 25° contains only one ion-pair for each 500,000,000 molecules (and this proportion decreases as the temperature falls), chemists will view with profound scepticism the suggestion that ice is ionised to the extent of 100 per cent. and contains no molecules at all; and they may even regard this suggestion as a *reductio ad absurdum* of the physical method of attacking chemical problems. On the other hand, when once the electrical structure of the *atom* has been accepted, chemists cannot avoid making mental pictures of the electrical structure of *molecules*; and these pictures have a definite value even when they cannot be reduced to precise physical forms.

Thus, although the idea of 'shared electrons' as an explanation of the chemical bond was introduced by Sir J. J. Thomson before the nucleus atom was invented, we are indebted to Prof. G. N. Lewis for exploiting the general proposition that it takes two of these shared electrons to make a bond; and this general proposition is now so firmly established that physicists may look upon it as a chemical fact for which a physical explanation must ultimately be devised, although at present we do not know in what way a pair of electrons can come under the control of two atomic nuclei, or why a binuclear orbit should be occupied by two electrons.

Dr. Sidgwick's book is an attempt to review the ordinary facts of chemistry in the light of the electronic structure of matter. It differs from previous books on the same subject, mainly in that attention is paid to the classification of the electrons into groups and sub-groups having a common principal or subsidiary quantum number. The most characteristic feature of the book is therefore a tentative classification of the *shared* electrons of chemical compounds, on the lines of the well-established spectroscopic classification of the *unshared* electrons of free atoms and ions. Such a classification must be mainly speculative, since it has at present no clear physical basis; but it may nevertheless prove to be of real value as an essential stage in the development of a combined attack by chemists and physicists on a problem which is of vital interest to both. In particular, the interpretation of chemical facts in terms of a purely empirical electronic theory of valency (and theories of valency have always been empirical) may be the only way in which the overwhelming array of chemical facts can be collected and masticated with the view of ultimate digestion. Thus, a very elementary static theory enabled Prof. G. N. Lewis to demonstrate the dual character of chemical affinity (typified by the *transfer* and the *sharing* of electrons) which the earlier chemical theories of valency had persistently sought to unify, and thus made it possible to harmonise the antagonistic valency theories of van 't Hoff and Werner.

This dual classification of *single bonds*, which is still the most important contribution made to chemistry by the electronic theory of matter, leads logically to the conception of polar, non-polar, and semi-polar *double bonds*, and a corresponding series of *triple bonds*, and in this form appears to cover all the main facts of chemical combination. It therefore seems likely to provide a permanent basis for all future theories of valency, with perhaps a grudging admission of a limited number of exceptions.

The most important of these possible exceptions are the *one-electron bonds* which Sugden has used as a means of maintaining Lewis's octet rule in compounds where groups of 12 electrons would otherwise be called for to represent the six 2-electron bonds of a 6-co-ordination compound. Sugden's very large group of exceptions, however, is narrowed down by Dr. Sidgwick to a few conspicuously unstable compounds, comparable with the 1-electron system, H_2^+, which can be detected in high vacua by means of the mass spectrograph. Dr. Sidgwick therefore admits the existence of 1-electron bonds amongst the unstable hydrides of boron; but even these exceptions to the general rule are only made necessary by the assumption that, since spectroscopic evidence proves that a large amount of energy is required to remove the *K*-electrons from an atom of elementary boron, the sharing of these electrons with a second atom of boron in the molecule of a boron hydride is impracticable. This assumption is open to question, since the balance of energy required can at present only be set down as the difference of a large known quantity and a similar unknown quantity, which may perhaps also be large.

The *three-electron bonds*, used in Thomson's formula for benzene, represent another type of exception, which appeals strongly to many chemists as supplying a physical basis for certain theories of residual affinity; but, since the parachor of benzene is in harmony with Kekulé's formula, it is doubtful how far even this very attractive exception is justified when the static condition of chemical molecules is under consideration, as contrasted with the possible existence of transient 'activated' forms.

Dr. Sidgwick's own principal contribution to the electronic theory of valency has been in connexion with the 'co-ordination compounds' which formed the subject of his presidential address to Section B (Chemistry) at the Leeds meeting of the British Association. These compounds were (and still are) widely known as 'molecular compounds,' *i.e.*, as compounds formed by the union of integral m[illegible]cules, instead of free atoms. The rules and many of the facts of co-ordination, culminating in the development of a new type of optical activity, were discovered by Werner; but they were associated with a confused (although definitely dual) conception of valency, which he would have been the first to clarify if he had lived to read G. N. Lewis's (1916) paper on "The Atom and the Molecule." These molecular compounds do not obey the ordinary rules of valency, although they conform to the rules of co-ordination. They were first brought into the general scheme of the electronic theory of valency in 1919, when Langmuir suggested that, in the platinum ammonia compounds, such as $PtCl_2$, $4NH_3$, the "NH_3 radicals are held directly to the platinum, each sharing a pair of electrons," so that "all these compounds should be looked upon as typical primary valence compounds," that is, as compounds in which a quadrivalent atom of nitrogen is united to the metal by two shared valency-electrons. In 1921 he applied the same ideas to the metallic carbonyls, $Ni(CO)_4$, $Fe(CO)_5$, $Mo(CO)_6$, which can be regarded as molecular compounds of carbon monoxide with a metal; he therefore assigned to these compounds valency formulæ, which have recently received a remarkable vindication from the discovery of chromium carbonyl, $Cr(CO)_6$, by Prof. Job in the laboratories of the Sorbonne.

Langmuir's suggestion that co-ordination a ds e sharing of a pair of electrons, derived w n one of the components, has been adopted gwick as the fundamental feature of the theory of co-ordination with which his name is now sometimes associated. In order to illustrate that theory, he suggests that the union of ammonia with a metallic chloride may be compared with the action of ammonia on methyl iodide,

$$[CH_3I]+NH_3 = [CH_3.NH_3]^+I^-,$$

since in each case the molecule of ammonia can only enter the inner sphere of affinity by displacing an atom of halogen from it in the form of a halide ion. The process of co-ordination therefore involves: (i) *the formation of a real bond* between the molecules or ions that are undergoing co-ordination, just as a bond of the ordinary kind is formed between carbon and nitrogen when methyl iodide and ammonia unite to form methylamine hydriodide; and (ii) *the transfer of an electron* from one atom to another, just as (in the same interaction) the nitrogen of the ammonia gives an electron to the iodine of the methyl iodide, and thereby acquires a positive charge to balance the negative charge of the iodide ion.

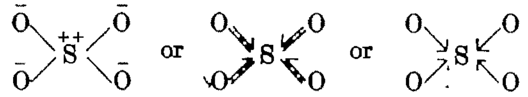
Whilst, however, Dr. Sidgwick has done much to clarify our conception of co-ordination, and to bring it into line with other forms of chemical combination, he is doing a real disservice by attempting to extend the use of the word to include not only all the main types of molecular compounds to which it is commonly applied, but also a large proportion of the oxidation products known to chemistry. For this extension there does not appear to be any warrant in current literature, since the burning of carbon monoxide to carbon dioxide, the electrolytic oxidation of potassium chloride to potassium chlorate or perchlorate, and the conversion of a sulphide to a sulphone, all lie outside the scope of existing definitions of co-ordination; and only ambiguity and confusion can result from an attempt to alter the meaning of so well-established a term. None of these oxidation products is in fact a co-ordination compound in the generally accepted meaning of the term, and the only analogy is found in the fact that, when an atom of oxygen is added to a chloride ion (or indeed to any system carrying a complete octet or shell of electrons), the two shared electrons which provide the bond of the oxide are both derived from the complete octet, whilst the half-molecule of oxygen contributes only a sextet to the final system.

If these two electrons are shared equally by the two atoms which they unite, the oxidation must be accompanied (as I pointed out in 1923) by the development of a negative charge on the oxygen and a positive charge on the other element, exactly as in the process of co-ordination. The atoms are then united, on one hand by a non-polar bond or co-valence, and on the other hand by an ionic linkage or electrovalence, similar to that which unites the sodium and chloride ions in common salt or the ammonium and chloride ions in sal-ammoniac,

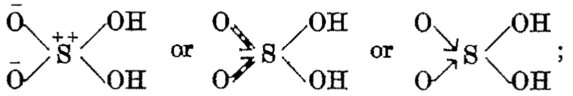
$$e.g.\ NMe_3 + O \longrightarrow \overset{+}{N}Me_3 - \overset{-}{O}\ (\text{compare } \overset{+}{N}H_4 + \overset{-}{Cl}).$$

This dual linkage, which was first described as a 'mixed' double bond, is described by Sugden as a 'semi-polar' double bond; but Sidgwick now proposes to call it a 'co-ordinate link.' This name is again unfortunate, since the transfer of an electron, which accompanies the process of co-ordination, may either create a charge on the atoms of a neutral molecule, as in the formation of an ammoniate, or may get rid of it, as in the formation of a platinichloride, $2\overset{+}{K}\overset{-}{Cl} + PtCl_4 = K_2^{++}[PtCl_6]^{--}$, where the chlorine atoms in the product are regarded as neutral (just as in CCl_4), since the electric changes which they formerly carried have been transferred to the metal. In the product, therefore, Sidgwick's own theory indicates that the co-ordination compound is held together by ordinary non-polar bonds, which are abnormal only in that the anion carries a negative charge. Since one of the two main groups of co-ordination compounds does not contain the type of union which it is proposed to describe as the 'co-ordinate link,' this new term appears to break down, not only by covering too much ground when including the oxides, but also by covering too little ground in excluding the co-ordination compounds of ionised salts.

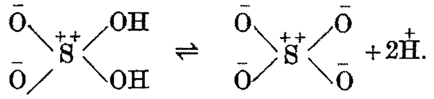
Finally, reference may be made to the symbol which Dr. Sidgwick uses to represent the 'mixed' or 'semi-polar' bond, or the 'co-ordinate link' of his own nomenclature. Since a single arrow has been used extensively by Robinson and others to represent a process of 'electron drift' in a single bond, there is a real risk of confusion in Dr. Sidgwick's use of this same symbol to represent a homopolar single bond on which an electrovalence has been superposed, as in the oxide $\overset{+}{N}Me_3-\overset{-}{O}$, especially as Robinson's electron drift would ultimately have the effect of *breaking* or ionising the homopolar bond, whilst the electron transfer represented by Dr. Sidgwick's symbol has the converse effect of *making* a bond between two molecules or ions which were previously quite free from one another. In this respect, Sidgwick's symbol is definitely inferior to the symbol $\rightleftharpoons$ introduced by me in 1922, which Sugden has used so extensively for this purpose. Both symbols are, however, inferior to the alternative (which is expressed by Sir Joseph Thomson's phrase 'intermolecular ionisation') of showing by means of plus and minus signs the charges on the individual atoms, or (more accurately) the relationship between the nuclear charge of the atom and the number of its quantum orbits which are occupied by electrons. Thus we may write the sulphate ion as:



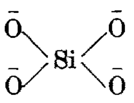
and sulphuric acid as



but the first of these symbols is the only one which shows that there is no direct change in the single bonds between sulphur and hydroxyl when sulphuric acid is ionised



In the same way, the analogous formula for the orthosilicate ion,



, is the only one which shows that the negatively charged oxygen cannot form a true 'semi-polar' bond with the silicon atom, since this atom is neutral and no longer carries a surplus positive charge.

Whilst a large part of Dr. Sidgwick's book is necessarily concerned with co-ordination and its various applications, the other forms of chemical combination are also adequately discussed. Thus the physical evidence for the nuclear atom, with its quantised electron orbits, forms the subject of two preliminary chapters; and the nature of the chemical evidence which led Main Smith to anticipate Stoner in re-arranging the quantum groups in the periodic classification of the elements is indicated much more clearly than in Smith's own book. General rules are also given whereby the author not only proposes to distinguish the physical properties of an ionised salt from those of a non-ionised compound, but also claims to be able to distinguish a covalent compound from a chelate co-ordination compound. In many cases these distinctions can be made with some confidence, as in the case of mercurous iodide, where the colou[illegible] the compound agrees with the X-ray analys[illegible] the crystals in showing that the compound is n[illegible] mere aggregate of univalent ions, $\overset{+}{Hg}\overset{-}{I}$, but mu[illegible] consist of covalent molecules, probably of the structure I.Hg.Hg.I. In other cases, however, the evidence is much less clear and the conclusions arrived at are less certain. Thus, in the rather difficult case of tellurium, the diagnosis appears to be based on a somewhat incomplete study of the symptoms, and will almost certainly have to be reconsidered as further knowledge becomes available.

The possibility that drastic revision of some of these preliminary conclusions may be called for does not, however, destroy their value, since, if they succeed in provoking further experimental work, they will have fulfilled one of the principal functions of a theory. At the same time, the reader would be well advised not to let the attractiveness of the picture obscure the tenderness of many of the threads of the canvas on which it is painted, since the author does not always emphasise sufficiently the reservations underlying his statements. If, however, when the author writes "it has been proved" the reader will mentally substitute the more accurate phrase "it has been suggested," and if when he writes "this must be due" the reader will read "this is generally believed to be due," no great harm will be done by the rather over-confident way in which the author's very fascinating views are put forward. There is also a risk that injustice may be done to earlier workers, owing to the fact that the origin of the views adopted by the author is not always indicated clearly. In particular, the section on the "Electronic Interpretation of Co-ordination" does not contain any reference to the paper, published in 1919, in which Langmuir anticipated the essential postulates of the theory of co-ordination advanced by the author in 1923. In the same way, the sections on the co-ordination of hydrogen might be strengthened by including a reference to the very clear statements on this subject which were made by Pfeiffer so long ago as 1913, and by Dimroth in 1921.

The last chapter of the book is devoted to a preliminary survey of the families of elements which make up the periodic table, with the view of finding an electronic interpretation of the chemical data, based on the known structure of the atoms and the known behaviour of the valency electrons. This survey is intended to foreshadow the contents of a new volume, in which these problems can be discussed more fully; but the value of that volume, when it appears, may be enhanced considerably by the fact that the author has been bold enough to put his first impressions into print, perhaps with the expectation that they may form a target for constructive criticisms.

Since the work of interpreting chemistry by means of physics may be one of the main tasks of the next decade, Dr. Sidgwick's book will be welcomed by workers in both branches of science, and all the more so from the attractive form in which it is presented. It is not an easy book to read, but (with one exception) the chapters are short, averaging less than 20 pages, so that they can be studied, one unit at a time, without undue effort; and the publishers have done their share in contributing to the pleasure of reading the book.

T. M. Lowry.

Phosphatic Fertilisers.

Phosphoric Acid, Phosphates, and Phosphatic Fertilisers. By Wm. H. Waggaman. Assisted by Henry W. Easterwood. (American Chemical Society Monograph Series.) Pp. 370. (New York: The Chemical Catalog Co., Inc., 1927.) 7.50 dollars.

THIS book is the thirty-fourth publication of the American Chemical Society Monograph Series, the purpose of which is to present to chemists as a whole the collected information on a chosen subject in a readable form and to show the problems that still await investigation. Exceedingly numerous are the references to the literature, and these will be of the greatest value to those readers who wish to pursue the subject still further.

Ever since the value of artificial fertilisers in agriculture was established, phosphoric acid has been considered mainly in this connexion. While in the past this essential plant food was given in the form of superphosphate, basic slags, rock phosphates, guano, and bones, only the first three of these are now available to any extent as fertilisers. The reserves of guano are becoming exhausted and the supplies are consequently limited. Bones are of importance in other industries. The ideal phosphatic fertiliser should combine good 'availability' with cheapness and be at the same time a high-grade product, for freightage has to be taken into account.

Judging the three fertilisers now in use by these standards, the water-soluble phosphate has the greatest possibilities, for by development and improvement of methods of manufacture the grade can be increased and price reduced. Basic slags are the by-product from steel works and of comparatively little value to the makers; the chances of improving their agricultural value are very remote. With regard to rock phosphates, though both high-grade and attractive in price, they are slower in action. Of recent years they have undoubtedly been used to a larger extent, but this would appear to be due to the fact that price and proximity of supply—they are well distributed over the world, so freightage is reduced—are important factors. Even now, however, the world consumption of superphosphate is greater than that of either rock phosphate or basic slag. Thus if any advance—which is long overdue—can be made in the phosphate industry similar to that which has taken place in the manufacture of nitrogenous fertilisers, the future would seem to be with the water-soluble phosphates. This is a topic of much general interest. In consequence, Messrs. Waggaman and Easterwood's book should be valuable to many, for in the main it deals with this subject. In addition, the growing importance of phosphoric acid in other industries is shown very convincingly. Of the relative merits of the phosphatic fertilisers now in use it has little to say, for there is still much controversy on the subject. Nevertheless, information on that matter from one so well qualified as Waggaman would have been welcome.

The book as a whole describes (1) the importance of phosphoric acid in bio-chemical and industrial processes, and (2) the sources and types of raw phosphatic material available, (3) methods for converting these into commercial products, (4) the economic production of phosphoric acid. Part I. is a general outline, but its value is greatly enhanced by the numerous references to the literature; an expansion of this part, the inclusion of references to some of the more recent work, and omission of the section on elemental phosphorus and its compounds would have been preferable. The sources and types of raw phosphate material, their conversion into fertilisers, etc., are treated in considerable detail and to those in any way connected with this trade it should be valuable. With regard to basic slags, their agricultural value in Great Britain and Ireland, at least, is not in full agreement with the results, taken from 1911 experiments, quoted in this book. Of the economic production of phosphoric acid the authors have much to say. The senior author has taken an active part in the development of the pyrolytic process and other problems, so that the conclusion that phosphoric acid will be a serious rival to other inorganic acid comes from a very authoritative source.

" Phosphoric Acid, Phosphates, and Phosphatic Fertilisers " fulfils admirably the purpose of this series, giving a clear and full account of the subject, especially the industrial side. The authors' views on the future development are supported by a veritable mass of data, while the numerous illustrations make the book attractive.

Geography and Anthropology.

Environment and Race: a Study of the Evolution, Migration, Settlement, and Status of the Races of Man. By Dr. Griffith Taylor. Pp. xv + 354 + 6 plates. (London: Oxford University Press, 1927.) 21*s.* net.

THE racial history of man cannot be elucidated by the physical anthropologist alone. The most that he can do is to describe the physical characters of large or small groups of men, recent and extinct, and to indicate their inter-relationships. The historian, or collector of legendary history, may throw some light upon past movements of the population, and the contemporary observer can record what movements are in progress or took place in the immediate past. The biologist, using that term in its widest sense, may make suggestions as to the factors of evolution, physiological, psychological, and others; as to the phenomena of miscegenation, heredity; and various other influences and processes.

Some of these aspects of anthropology are conditioned by the physical environment of a given people, but even an environmental study does not suffice, since it is necessary to understand the former geographical and climatic conditions which were operative upon the ancestors of that people. We know that practically all peoples have been subjected not only to an environment different from that in which they now live, but also that their environment continually varied, land was raised or submerged, and there were major and minor fluctuations of climate. Also, it is necessary to know the relief of the land, the rainfall, and other data, in order to learn what areas were favourable for human existence, those that served as corridors and those that acted as barriers, and so facilitated or inhibited human movements.

These studies are the province of the geographer, and although partial studies of this kind have been made, which have been published in various books and journals (some of which are likely to escape the notice of anthropologists), they have never previously been assembled in a single book; th[illegible] a general survey of the world on these lines has be[illegible] beyond the scope of the anthropologist. If only for this effort, anthropologists owe a great debt to Prof. Griffith Taylor for his " Environment and Race." In considerations of this kind, a time scale is necessary, and it is mainly to the geologist that anthropologists must turn, and our author, naturally, has not neglected this aspect. Although culture has nothing to do with race, we do find that certain languages, customs, ideas, and objects have a particular range in space, and doubtless some of them were restricted in their origin to a definite group of people; here the linguist, the sociologist, and the technologist come to our aid; the subject of fossil technology, or archæology, for example, is invaluable in tracing the movements of ancient cultures; but the diffusion of cultures in some cases may to a large extent be independent of racial migrations, a fact which the author seems to have overlooked.

For the past and present setting of the stage for mankind, Prof. Griffith Taylor provides a most admirable survey. Within the compass of a small book it was obviously impossible for him to go into that detail which a student of a given area might require, but the broad lines here sketched out will prove an invaluable preliminary to more intensive research—it may here be noted that the loess belt of Europe has been overlooked, though it formed an important migration route.

The book is an amplification of suggestive articles that have appeared in the *American Geographical Review*, 1919, 1921, 1922. The thesis is maintained that man originated in central Asia and thence Neanderthal (with which Proto-Australian, *e.g.* Talgai, etc., are associated), Negrito, Australoid, Negroid, Iberian, Nordic, early and late Alpine (*i.e.* Mongolian) stocks debouched in this order and passed, but not necessarily all of them, along the corridors of the peninsulas of central Asia—Europe, Africa, Australia, and America; the earlier propulsive forces being the climatic thrusts of the four main ice ages. This theory presupposes that increase in the cephalic index (C.I.) took place only in the centre of Asia, and though it is worked out with ingenuity it is unlikely to receive the support of anthropologists.

The argument is based on averages, and does not take into account the considerable fluctuations that occur in the groups. Thus the Lower Negroes, "Peoples of Guinea and Upper Nile," are credited with a C.I. of 71 (parallel with the South Melanesians and New Guineans); the Wolofs of Senegal are said to have a C.I. "as low as 69," but Struck gives it as 74·3; and the author credits the Higher Negroes, "Bantu-speaking Negroids," with a C.I. of 73 (parallel with the Australians). B. Struck has prepared a well-documented "Karte des Kopfindex" of central Africa (*Z. f. E.*, 54; 1922), from which it is evident that the averages of peoples of Guinea and the Upper Nile Valley vary from 71 to 75, few being 71 or less, but also in the former region there are numerous peoples with average C.I. of 75-79, while in the Cameruns and Congo basin average indices of 77 to 81 are common, with patches of above 81. According to Griffith Taylor's scheme, these Negroes should be Hamites, Semites, Aryans, and early Alpines; but we are told that the "vast central and southern block of negroes has not been greatly affected by recent mixture" (p. 106). A similar objection applies to other areas.

From Appendix B, it is evident that the author still adheres to his previously published opinion that various customs, etc., characterise definite zones of cephalic indices. In 1921 he said, "the couvade occurs in the Hamitic-Iberian zone [C.I. 76-78] *and nowhere else*," but the Carib C.I. of 80·9 and the Arawak of 83 are hard to reconcile with this generalisation, and other cultural distributions are equally open to question. It is doubtful whether any ethnologist will accept this theory of zonal cultures. A new feature is the introduction of 'ethnographs,' in which certain physical characters are combined to form a hexagon, the proportions of which vary according to race. The book is illustrated by a number of racial types, and especially useful is the large number of distribution maps and block-diagrams.

The book concludes with valuable discussions on "the white race in the Australian environment" and "the control of the potential white settlement of the world by environment." In these sections Prof. Griffith Taylor speaks with authority based on solid facts, and they should be carefully studied by prospective emigrants and also by politicians.

A. C. HADDON.

Our Bookshelf.

Rules for Compositors and Readers at the University Press, Oxford. By Horace Hart. The English spellings revised by Sir James A. H. Murray and Dr. Henry Bradley. Twenty-eighth edition. Pp. 135. (London: Oxford University Press, 1928.) 2*s*. net.

THIS little book was not originally intended for publication. When it was begun the intention was simply to make a guide for compositors and readers at the Clarendon Press. But copies were also given to those who were interested, and, later, applications for copies were received from persons who had no absolute claim to be supplied gratuitously. Many such requests came from Home, Colonial, and Indian Government officials. That is a recommendation in itself; and the recommendation is heightened when we learn that, later, it became known that copies were on sale in London. Clearly there was no alternative but to publish the book for the benefit of all those who are interested in the technicalities of typography; and there can be no doubt that it confers great benefits not only on those engaged in the art of printing, but also on those whose business it is to write.

The book includes, of course, the ubiquitous (but none the less necessary) guide to proof correction. But there is also an alphabetical list of alternative and difficult spellings; there is a list of spellings for use in medical works, divided into words with, and words without, hyphens; there are rules for setting up French, German, and Greek works; there is advice on the question of spacing—a matter which is ordinarily full of annoyance for both printer and author; special signs and symbols are made clear; and sufficient attention is paid to the use of punctuation, O and Oh, a and an, to save much impending irritation. It is not possible here to indicate the full scope of the book. It is a work of reference, and, as such, may be expected to be a mine of *easily accessible* information; that expectation is certainly fulfilled.

The American Annual of Photography, 1928. Vol. 42. Edited by Frank R. Fraprie and E. J. Wall. Pp. 224 + 68. (Boston, Mass.: American Photographic Publishing Co.; London: B. T. Batsford, Ltd., 1928.) Paper, 7*s*. 6*d*.; cloth, 10*s*.

THIS annual has several distinguishing features. The "Practical Digest of the Year's Work in Photography," by Mr. Wall, is a readable and discriminative article with occasional valuable criticisms. The formulæ of developers, etc., are all tabulated on the same unit, and each table, which includes those of a like kind, has the average formula appended to it. There are more than ninety pictorial illustrations, and an article directing attention to their characteristics by Mr. Fraprie.

Of the sixteen other articles, the one of outstanding interest is on "Photography through the Microscope," by E. P. Wightman and A. P. H.

Trivelli. The authors not only describe modern developments in photomicrography, such as the use of ultra-violet light, modern methods of dark-ground illumination, and the application of the 'motion picture camera' to certain types of microscopic moving subjects, but also they give illustrations that are very little if at all inferior to the original photographs. Examples of the use of the ultra-microscope include pictures of *Pleurosigma angulatum*, collodion and gold films, a partial mirror of gold, normal blood platelets, soap crystals, and the germ of yellow fever. Those taken by means of ultra-violet radiations show remarkably fine definition, bearing in mind how difficult it is to find the focus in this method; and they clearly demonstrate the increased resolving power of the shorter wavelengths. The kinematographic photomicrographs show the gradual development of silver bromide grains, the growth of silver sulphide specks on the surface of fused silver bromide, the absorption of water by a crystal of salt in butter, and the formation of colloidal bismuth and its subsequent coagulation. These and several other photomicrographs, of both high and low power, were supplied by experts in the various branches of work represented

God is Love. Can this be True? An Old Man's Meditations. By Dr. James M. Wilson. (Affirmations: God in the Modern World.) Pp. 31. (London: Ernest Benn, Ltd., 1928.) 1*s.* net.

RELIGION is closely concerned not merely with the problem of the existence of God, but also with the even more pressing problem of His character. God might exist, and yet not be the kind of being man could worship. Canon Wilson clearly realises that the God of biological science scarcely resembles the God of Love whom we read of in the New Testament. How are we to reconcile these opposites?

Canon Wilson's method is to evacuate his God of transcendence and personality, and to present Him as purely immanent Spirit, in the conscious possession of which Spirit men may find sonship with God. This solution, while emphasising the, to religion, indispensable consciousness of union with God, has its dangers too. Indeed, what solution has not? If we divest God of transcendence and personality, the God of biology may wear a more tolerable aspect, since the sufferings He imposes are His own, and since (if He is impersonal) He does not really know what He is doing. But what we gain in one way, we lose in another; for the God of religion, divested of transcendence and personality, seems no longer worshipful. Personality is a supreme value, and whatever falls short of it seems unworthy of worship. As for the immanent God, the God within us, if we begin by worshiping *Him*, shall we not end by worshipping ourselves?

We may, however, be grateful to Canon Wilson for approaching this most difficult subject in a spirit of candour and deep religious faith.

J. C. HARDWICK.

Archimedes: or The Future of Physics. By L. L. Whyte. (To-day and To-morrow Series.) Pp. 96. (London: Kegan Paul and Co., Ltd.; New York: E. P. Dutton and Co., n.d.) 2*s.* 6*d.* net.

THIS little book appears at an opportune moment. It is generally acknowledged that the accepted principles of theoretical mechanics break down at the boundary of the atom, and some new system will have to be devised which will make the internal structure of atoms amenable to mathematical treatment. The main issue of the crisis is the subject of the controversy between Einstein and Eddington on one hand and Bergson and Whitehead on the other. The author tries to fathom the meaning of this modern duel and to forecast the manner in which it will be eventually settled. He directs attention to the fact that the laws formulated by Einstein deal with reversible phenomena. Real processes in Nature, on the other hand, are irreversible. "It may be that the reason why we cannot interpret atomic behaviour in terms of particle motions is that electrical and radiational processes are essentially irreversible. Particle motion and wave propagation—the two ideas on which all modern theories of matter are based—are both represented by mathematical expressions which are essentially reversible, since time enters only through the square of '*dt*'. If the quantum processes should prove irreversible, we have already found a reason why the old conceptions of particles and waves must be inadequate."

The author draws a suggestive analogy between radiation and life processes, both of which are essentially irreversible.

La géométrie non euclidienne. Par Prof. P. Barbarin. Troisième édition suivie de notes sur la géométrie non euclidienne dans ses rapports avec la physique mathématique, par Prof. A. Buhl. (Collection Scientia, No. 15.) Pp. 176+7 planches. (Paris: Gauthier-Villars et Cie, 1928.) 15 francs.

AN interesting and brightly written introduction to non-Euclidean geometry, with an appendix of notes dealing with its relations to the theory of relativity. There are plenty of references and several plates, including portraits of the heroes of the subject, Bolyai, Lobatschewsky, Riemann, and a fascinating picture of Beltrami's pseudosphere. It is an extremely good half-crown's worth.

Les bases de la géométrie et de la physique: l'invariance de l'espace euclidien. Par Clément Laurès. Pp. iii+125. (Paris: Albert Blanchard, 1928.) 15 francs.

THE author claims to have proved Euclid's postulate of parallels and to have pointed out the errors and contradictions of Lobatschewsky. The book is an attack on non-Euclidean geometry and the theory of relativity, which M. Laurès describes respectively as "une des plus stupides inventions du XIX^e siècle," and "une autre stupidité, fille aînée de la première."

Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

The Production and Application of High Voltages in the Laboratory.

The importance of the application of high voltages to vacuum tubes is self-evident. Its possibilities in connexion with radioactivity have been emphasised lately by Sir Ernest Rutherford.[1] For the last two years we have been occupied in developing a laboratory method for the production of high voltages in a form suitable for application to vacuum tubes. Our problem divided itself into two parts: (*a*) The production of high voltages; (*b*) their application to vacuum tubes.

(*a*) The method for producing high voltages is based on old and well-known principles. A condenser of the order of 0·5 microfarad is charged to a potential of the order of 50,000 volts and suddenly discharged through a small inductance and a spark gap. The inductance is coupled to a resonance coil of the type usually referred to as a Tesla or Thomson coil. It was immediately obvious that very high potentials can be obtained with moderate means. Our coils were wound on pyrex tubing 3 inches in diameter and 36 inches long. The number of turns was in the neighbourhood of 7000.

The main difficulties to overcome were the insulation of the ends of the coil and of the turns from each other. We found ordinary transformer oil to be capable of insulating coils for 3,000,000 volts at atmospheric pressure, and for more than 5,000,000 volts at 500 pounds per square inch. No extraordinary precautions as to purity of the oil or otherwise were used, and do not seem to be necessary for these voltages. Spherical caps were mounted in the usual manner on the ends of the coil. By using the coil on half wave-length, the gradient at the caps corresponded to one-half of the total voltage. The coils were subjected to rough vacuum impregnation perhaps as a matter of prejudice. Our limitation at 5,000,000 volts was in the insulation between turns with this particular length of coil. Ordinary No. 40 silk enamel covered wire was used. The ends and the electrical efficiency are capable of giving considerably higher voltages with the present arrangement. Since 5,000,000 volts, when applied to doubly charged helium atoms, or particularly to α-particles, and still more to multiply charged ions (stripped atoms), should be capable of giving particles with energy much in excess of the swiftest α-particles so far observed, we temporarily transferred our efforts about a year ago to the problem of applying voltages of this order to vacua.

The method of measuring the voltages may be described as a capacity potentiometer. The apparatus consisted in an insulated metal 'pick-up' ball suitably placed in the field of the coil and connected to one terminal of a 10-inch sphere gap, the other terminal of which was earthed. By a preliminary calibration at the same frequency, the ratio of the coil potential to the pick-up potential was determined at low voltages on the latter (about 100 volts). This calibration involved a study of the voltage distribution along the coil, the details of which we will report later. A knowledge of this distribution made it possible to infer the voltage across the whole coil by measuring the voltage across a small section, thus eliminating capacity effects of the measuring instrument. We took care to ascertain experimentally the effect of the distance between the two balls of the gap. These calibrations have been performed under various conditions with entirely different set-ups, giving always consistent values for the voltage obtainable with a given input.

We have also performed rough calibrations in which the Tesla coil voltage was measured directly by means of a sphere gap and simultaneously by the capacity potentiometer. Due care has been taken in this case to reduce the effect of the leads to the direct gap on the potentiometer.

The order of magnitude of the voltage has also been ascertained by measuring the field strength at a distance by means of a cathode-ray oscillograph and applications of electrostatics.

The doubts which might be raised as to the correctness of our sphere-gap measurement seem to be two: The truthfulness of the sphere gap and the absence of conductivity in the oil. Our frequencies being of the order of 100,000 per second, the correctness of the sphere gap is proved by the work of Peek.[2] The extrapolation applied to the capacity potentiometer from low to high voltages we have tested in various ways. Thus the position of the pick-up was varied, giving always consistent results. The spark-over between turns on especially tested wire always leads to higher voltages than those measured. The voltage measured is proportional to the voltage applied to the primary circuit. At the same time, the direct effect of the primary circuit on the pick-up is negligible.

(*b*) After trying discharge tubes of ordinary design, it became obvious that limitations somewhat similar to those experienced at low frequencies apply to high-frequency voltages as well. The application of more than 400,000 volts in an ordinary way appears to be difficult, apparently due to the fact that methods of completely outgassing an entire electrode (including the part close to the glass) have not yet been devised.

However, we found it quite possible to apply several times the above voltage to a vacuum without electrodes inside the tube, making use, therefore, of the fact that our voltages alternate at high frequency. In this arrangement we have a 9-inch, well-baked and evacuated bulb placed, using approximately 1 mm. spacings between the end of the Tesla coil and an earthed plate. Fluorescence of long duration is caused on the sides of the bulb, but no volume discharge takes place and the bulb does not puncture. An ionisation gauge on a side tube does not give any difficulty. If the pressure in the bulb is raised, a bolt strikes through 2 inches of oil and makes a large hole in the bulb.

The question of the power available in a Tesla coil is of some importance. Experimental tests show that coils of our usual design with a given power input have their voltage reduced by a factor of 2 if a 16-megohm leak is connected across the terminals. If the coil is used on a 60-cycle synchronous gap, and if the energy dissipation only during 10^{-5} sec. for each spark is considered, the power which may be drawn from a coil operating at 5×10^{6} volts is readily seen to be at least of the order of 1 kilowatt.

Even with one discharge a second considered as taking place effectively in producing high-voltage particles for 10^{-6} sec., *i.e.* for $\frac{1}{10}$ of a cycle, a number of electrons equivalent to 10 gm. of radium could be supplied by the Tesla coil without overstepping its electrical power limitations. On the same basis, a gap operated on 60-cycle current giving 120 sparks a second would enable the Tesla coil to deliver the equivalent of 2 lb. of radium.

[1] E. Rutherford, Nature, 120, p. 809; Dec. 3, 1927.

[2] F. W. Peek, jun., *Jour. Franklin Inst.*, 197, p. 1; 1924.

It is clear that the outside electrode method of using vacuum tubes does not make it possible to use all of this power. However, a transfer of 2×10^{11} electrons would not puncture the glass. Estimates show that very considerable radium equivalents can be obtained even by the method of external electrodes.

An Optical Paradox.

Surely there is nothing peculiarly 'optical' in the 'paradox' to which Mr. Smith refers in Nature of Feb. 25. In respect of most measurable properties (for example, length and mass) systems can be arranged in a series such that each member, though indistinguishable from its immediate neighbours, is distinguishable from those more remote. In other words, the relations usually termed 'equality' in measurement are not transitive; though $A=B$, $B=C$, it does not follow that $A=C$.

That is a fact; paradox can enter only in describing it. Mr. Smith's description appears paradoxical, because the term 'identical' that he employs usually implies transitiveness. To determine whether a relation is transitive, at least three members of its field must be compared; accordingly, if 'identical' means a transitive relation, none of his comparisons, each involving two sensations only, can establish identity. It is *not* a 'quibble' to say that two sensations, A and B, indistinguishable when compared directly, are not identical; for they may be distinguished by the classes, C_A and C_B, consisting of sensations from which they are respectively indistinguishable. C_A and C_B always contain common members; but in general they are not coextensive, and each contains members foreign to the other. A and B are truly identical only if C_A and C_B are coextensive, and A is indistinguishable, not only from B, but also from every sensation indistinguishable from B.

In theory these considerations may be 'widely ignored,' but in practice they are not. Poincaré's suggestion that the theory of errors of measurement and of the adjustment of observations should be based on them has not been widely adopted. But, as I have tried to show in Chaps. xvi. and xvii. of my "Physics," it leads to practical rules for dealing with these matters closely resembling those in general use, which are more often based on the futilities of the Gaussian Gospel. Whenever we recognise the possibility of errors and take steps to avoid them, we are in effect giving full weight to Mr. Smith's considerations. Nobody experienced in photometry would actually compare lamps through a simple unidirectional chain such as he describes.

Norman R. Campbell.

A paradox, resembling that which Mr. T. Smith describes in Nature of Feb. 25, p. 281, was stated by G. F. Stout in his "Manual of Psychology" (1915), pp. 303 to 304, for senations in general.

For a particular sensation, that of weight lifted, the paradox was abolished by the experiments of F. M. Urban (*Archiv für gesamte Psychol.*, 5, 15, 16), for they showed that the threshold was not the definite thing that Mr. Smith assumes it to be, but that when one stimulus was kept fixed, the probability of the observer making the decision 'equal' varied with the other stimulus in a gradual manner.

Is the optical threshold unlike that for weight?

Lewis F. Richardson.

Westminster Training College,
Horseferry Road, S.W.1,
Feb. 29.

Dr. Campbell seeks to demolish the paradox by applying to sensations an argument constructed to take account of the variability of our measurements of the properties, believed to be constant, of external objects. Besides differing in other important respects, the two applications are unlike in that the presence of errors in our measurements is readily demonstrable by intercomparison, whereas the view that indistinguishable sensations are not in fact equal sensations is an arbitrary assumption which it would be difficult to support by direct evidence. This view is perhaps derived from the wish that it were permissible to regard visual sensation and light stimulus as definite single-valued functions of one another.

Now there may be occasions when it is convenient to postulate an idealised system of sensations bearing such a relation to a series of stimuli; but the concept is essentially theoretical, and must not be confused with the sensations of experimental photometry. Experimentally, sensation denotes an impression individual to the observer, an impression, moreover, of so fleeting a nature that group intercomparison is impossible. The observer's verdict on his sensations at any given moment is the only one that matters: if he says that two sensations are indistinguishable, we ought either to accept that statement as final or bring forward evidence to justify our distinguishing between them.

I am inclined to think that the physicist has been handicapped in considering the photometric problem by his expectation of a close correspondence between sensation and stimulus. It is characteristic of the way in which he has grown accustomed to regard his experiments that he should, without question, ascribe the sensation he associates with the left side of the field solely to the lamp on his left, and to the lamp on his right the sensation he associates with the right side of the field. I have little doubt that he habitually presses too far the view that sensations may be isolated. In photometry, particularly when the two parts of the field are nearly or exactly matched, we ought to regard the sensation as a function of both the stimuli. On this view the argument of the paradox fails, not because the two sensations in a single observation differ, but because we are not justified in isolating the two halves of the system from one another or in assuming an unvarying connexion between the radiation on the unaltered side of the system and the sensation in the part of the field we link with it.

More generally the principle to which I wish to direct attention is that every sensation is a function of all the stimuli. The principle is illustrated by the fact that the introduction of peripheral illumination may enable us to discriminate between sensations when differentiation was previously impossible. Dr. Campbell would perhaps explain this result by saying that the introduction of the additional illumination in effect constitutes the replacement of the old comparator by a better one. That view is, I think, legitimate, but it is not consistent with the assumption of an unvarying connexion between stimulus and sensation.

T. Smith.

The Soil 'Stratometer': A Method for the Examination of Deep-lying Soil.

IN alluvial soils there are frequently large variations of soil texture, especially in a vertical direction. With deep-rooting crops like cotton, the soil at depths of more than two metres may be directly important to the plant, quite apart from its indirect importance by influencing drainage, or infiltration under irrigation. The study of such deep soil by soil-boring and sampling has certain limitations, while its complete disturbance by digging large holes is even more objectionable and tedious.

Some infertile areas of the Botanical Section Farm at Giza were being examined for the presence of 'pans' when it was noticed that the mechanical resistance of the soil varied greatly, whether such resistance was felt by a Frænkel borer or by the use of the digging tool. From this observation was developed a simple instrument which has been entitled a 'stratometer,' whereby the variable hardness of soil along vertical lines can be found, giving results somewhat analogous to the records of variability on the surface, in a horizontal plane, which have been made at Rothamsted with dynamometers attached to ploughs (B. A. Keen, NATURE, Dec. 19, 1925, p. 905).

The present note is intended to put the actual method on record. Detailed studies of Egyptian soils by this method are being continued, and will be published later.

The method consists merely in driving a rod into the soil by repeated application of a uniform impact blow, as in pile-driving. The error which would otherwise be caused by increased friction on the sides of the rod as the depth increased is avoided almost entirely by the use of an enlargement like a spear-head at the point of the rod; this head is detachable to save trouble in removing the rod from hard soils, the head being left below and a new one fitted to the rod. The uniform impact blow is conveniently applied by a perforated weight through which the rod passes loosely; this weight rests and strikes on an anvil-stop clamped firmly to the rod, while the height through which the weight drops on to this anvil is fixed by a stop above it, also clamped to the rod.

The distance through which the rod descends at each blow is measured in any convenient way; a simple method is to fasten a tape just behind the head and to mark on the tape after each blow at the point where the tape passes through a zero level, indicated by a spiked plate driven into the surface soil with a hole through which the rod and tape both pass.

The tape-records may be afterwards computed and plotted in various ways, but usually it is convenient to show the hardness of successive strata, between 10 cm. or 20 cm. intervals, in terms of the energy required (*i.e.* number of blows) to traverse such intervals. The whole apparatus is very simple, can be made by any blacksmith, and a single set of observations down to two metres takes about ten minutes to make with two operators at work.

As an illustration of the information thus obtainable, the case of a 'pan' may be cited. The cotton plants in one corner of a field were stunted during mid-summer, recovering later. An exposure was made, and showed that their roots found difficulty in penetrating a layer at 30-60 cm. deep. Less than 15 metres away they were quite healthy. Soil water-content samples showed the hard layer to be impermeable to water also. The digging of pits showed an exactly similar distribution of clay above and sand below in both spots, the hardness and impermeability of the lower edge of the clay in the panned spot not being obvious except to the feel of the tools used in boring or digging. On applying the stratometer the difference was most strikingly revealed as a four- to five-fold difference in maximum hardness (Fig. 1).

If the stratometer impinges on a stone this is readily indicated by the sound as the blow is given, and the *sudden* and persistent resistance to the rod.

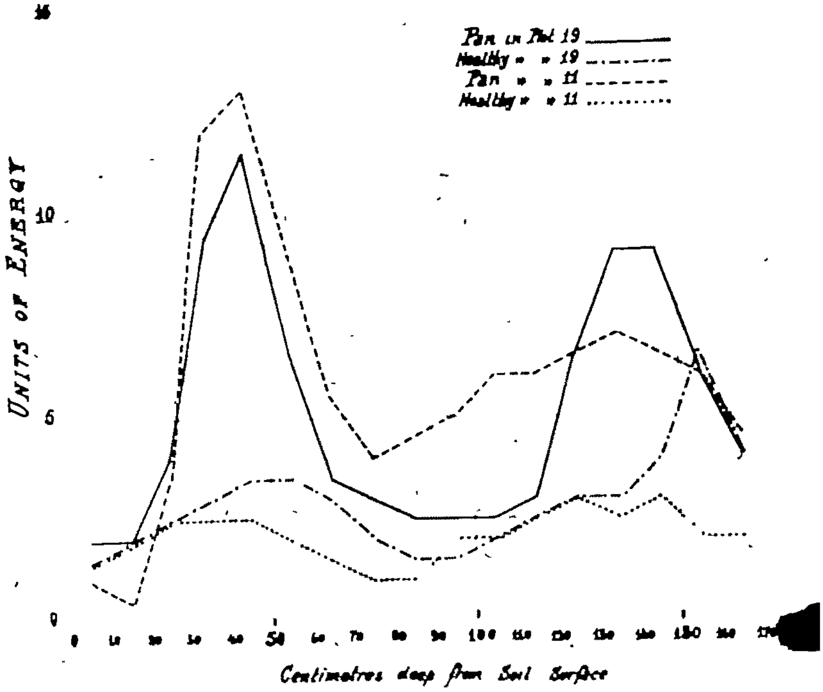

FIG. 1.—Graph of stratometer records.

The design of the rod for depths exceeding two metres needs care in order to avoid loss of energy by undue vibration, and the relation between water-content and hardness of soil is an obvious source of variability when comparisons over an interval of time are required. These are being investigated in conjunction with the direct employment of the stratometer for detailed survey of the deep soil and subsoil on particular areas.

The Nitrogen Afterglow.

THE phenomena connected with active nitrogen and its afterglow have recently received a great deal of attention. A view almost generally accepted now is that the afterglow is due to the recombination of nitrogen atoms produced in the discharge. Though it has not been possible hitherto to determine thermochemically the heat of dissociation of molecular nitrogen, a value a little above the equivalent of 11 volts has been found for it from the characteristics of its band spectrum. On the recombination of two atoms taking place to form a molecule this amount of energy may be transferred to a second molecule, and it is just sufficient to excite the afterglow bands. This view, it may be stated, is based on the assumption that the initial states giving rise to the first positive group of bands are the same as the final states involved in the production of the second and fourth positive group. The vibrational levels seem to be identical; the rotational levels have not yet been analysed.

What appeared to be a confirmation of this hypothesis was the discovery that foreign vapours such as those of mercury, zinc, etc., when mixed with active nitrogen, emitted radiations that required for their production electronic excitation not greater than the equivalent of 10 volts.

A closer examination of the spectra thus excited shows, however, that the intensity distribution obtained is not what one might expect to get from an energy transfer corresponding to that of 10 or 11 volts. With the spectrum of mercury, the rate of decrease of intensity in passing to the higher members of the series involved is much greater for excitation by active nitrogen than is obtained with a low voltage arc run at 10 or 11 volts in this vapour. Similarly, the intensities of the lines produced under excitation by active nitrogen in thallium vapour correspond closely with those obtained when the thallium lines are produced under excitation by the metastable atoms of mercury, which have an energy corresponding to about 5 volts:[1]

	Tl. $(2^2P_2 - {}^2S_1)$		$(2^2P_1 - {}^2S_1)$			$(2^2P - 3^2D)$			$(2^2P - 4^2D)$		
	5351,	3230	3776,	2580,	2826	3529,	3519,	2768	2922,	2918,	2380
In arc	10	10	10	8	8	8	10	10	6	10	8
In afterglow		6	2	1	0	4	10	8	0	8	–
In mercury	-	5	3	1	–	9		2	1	–	–

At the low pressures at which the nitrogen afterglow is studied, luminescence produced by chemical reactions is strong (formation of alkali halides, explosion of mercury compounds), so that it is not impossible that chemi-luminescence plays a rôle in producing the spectra excited by active nitrogen. It is well known that nitrides of metals, some of them explosive ones, accumulate in the discharge tubes used for the afterglow. With these considerations in mind, we recently decided to investigate the probability, by the use of active nitrogen, of causing an inert gas to emit its characteristic radiations. In such a case chemical changes would, of course, be excluded. If the view expressed above be valid, xenon with an ionisation potential of about 11 volts ought to emit its complete spectrum when mixed with active nitrogen. With the use of krypton the low level spectral lines should be obtained. These inert gases were therefore introduced into the discharge tube, and the spectrum of the light from the afterglow was photographed by means of a quartz spectrograph of high light power specially built in the laboratory for this purpose.

In the first series of experiments a mixture of krypton and xenon prepared in the laboratory was used and an excess of nitrogen was added. In the spectrograms obtained the afterglow bands were present, but no spectral lines due to the inert gases were recorded.

When, however, a drop of mercury was introduced into the tube and the spectrum of the afterglow again photographed, it was found that the mercury lines came out strongly on the plate in addition to the nitrogen afterglow bands. Very short exposures were required to bring out these mercury lines.

In a second series of experiments, very pure xenon was added to the nitrogen until the mixture was about half and half of each gas.

When an electrical discharge was passed through this mixture, the xenon lines showed up strongly in the spectrum of the light from the discharge, and the first positive nitrogen bands were almost completely suppressed. With this mixture the afterglow obtained was intense, but no xenon spectral lines were obtained on the spectrograms even when an exposure of twelve hours duration was made.

An experiment was performed to see if xenon radiation of wave-length λ8819 A., which is known to be strongly weakened when sent through excited xenon (J. C. McLennan and R. Ruedy, *Trans. of Royal Society of Canada*, vol. 32, p. 15; 1928), was absorbed by the xenon present in the nitrogen when the latter was showing a strong afterglow. No change could be detected, however, in the intensity of the xenon radiation sent through the glowing gas.

It would appear, then, that no xenon atoms were present in the gas in the metastable state ($^3P_2$ or S_5) that is known to be involved in the absorption of the wave-length λ8819 A. It is evident, therefore, that active nitrogen is not an agent that can cause xenon atoms to pass from the ordinary into the metastable state. The energy of the latter, it may be stated, is the equivalent of about 8·4 volts. It is interesting to recall that when, for example, zinc vapour is present in active nitrogen, spectral lines corresponding to 8·4 volts excitation are readily obtained. What happens with zinc vapour is obtainable with the vapour of any metal with which nitrogen can enter into chemical combination. The conclusion seems to be justified that chemi-luminescence plays a rôle in phenomena associated with active nitrogen.

Prices of Periodical Scientific Publications.

In view of Dr. Baini Prashad's letter on this subject in Nature of Mar. 31, perhaps the following information with regard to physiological and biochemical periodicals may be useful.

The statistics in the list below show that the total cost per annum of seven of the most important German physiological and biochemical journals is between three and four times as much as that of seven leading English ones, and also that the same German journals cost considerably more than do the more important physiological journals *of all the other countries together*. These figures, like those of Dr. Baini Prashad, are for the year 1927.

1. British.

	Vols. per year	Price per year.		
Biochemical Journal (Biochemical Society)	1	£3	0	0
British Journal of Experimental Biology (Company of Biologists, Ltd.)	1	2	0	0
Heart (Shaw and Sons)	c. 1	1	17	6
Journal of Physiology (Physiological Society)	2	2	10	0
Physiological Abstracts (Physiological Society)	1	2	2	0
Proceedings of the Royal Society, B.	1½	1	10	0
Quarterly Journal of Experimental Physiology (Griffin and Co.)	2	3	12	0
	9½	£16	11	6

---

[1] *Jour Opt Soc. Am*, 14, p 17; 1927. *Zeit f. Physik*, 29, p. 345; 1924.

2. AMERICAN.

	Vols. per year	Price per year.
American Journal of Physiology (American Physiological Society)	4	£7 4 0
Journal of Biological Chemistry (American Society of Biological Chemists)	4	6 0 0
Journal of General Physiology (Rockefeller Institute for Medical Research)	2	2 15 0
Physiological Reviews (American Physiological Society)	1	1 12 6
	11	£17 11 6

3. GERMAN.

	Vols. per year	Price per year.

	11	£14 12 0

The enormous output at present both in England and in Germany—still more so in America—renders it imperative that all published results should be as concise as possible, so that the research worker may be able to keep abreast of the material. One great difference between the British and German journals is that the former are edited far more rigorously than the latter. If the Germans followed our example in this respect, it is probable that they would be able to reduce their published biochemical matter by one-half.

If the Englishman finds the cost of German periodicals excessive, still more must the German physiologist himself find it so. When this matter was brought up at the International Physiological Congress at Stockholm the year before last, the suggestion was there made that the German physiologists should do their own printing: the Deutsche Physiologische Gesellschaft might well be utilised for this purpose, in the same way as the Deutsche Chemische Gesellschaft is used by the German chemists, thereby rendering German chemistry available to all at a very low price.

The only other remedy left for Great Britain is to discontinue subscriptions to the more expensive German journals. Dr. Prashad suggests that the Royal Society and similar bodies should take the matter up in the interest of workers. I am informed that the Council of the Royal Society at a recent meeting actually decided to discontinue a number of these journals, mostly published by Springer, and including Pflüger's *Archiv*, and the *Zeitschrift für Anatomie und Entwicklungsgeschichte*, thereby saving just under £100 a year, and setting an example which might well be followed by other societies and institutions, both in Great Britain and in the United States.

WILFRID BONSER.

Medical Sciences Library,
University College, London, W.C.1.

Woods and Wireless.

THE splendid paper read by Mr. Barfield at the meeting of the Institution of Electrical Engineers on Dec. 7 last, and referred to in NATURE of Dec. 30, 1927, p. 967, throws light upon the hitherto obscure mechanism of the damping by trees on the propagation of radio waves. In fact, every tree acts as a B.C.L., absorbing part of the energy falling upon the antenna, and re-radiating the rest.

May I lay stress upon the fact that a tree cannot possibly be regarded as a pure resistance, except when emission takes place on the resonant frequency of the tree. As, generally, the natural wave-length of the tree is shorter than the wave-length of the broadcasting transmitter, its action is that of a condenser with big losses. Translating to the language of Prof. Sommerfeld's beautiful solution, this means that the 'numerical distance' is not a positive real number, but a complex one. Writing his a^2 in the form $2a^2 = q(\cos b + i \sin b)$, we get, approximately, $q = 2\pi r/2c\lambda^2\sigma$, $\tan b = (\epsilon + 1)/2c\lambda\sigma$, the symbols having their usual meaning, and with σ in E.M.U., ϵ in E.S.U.

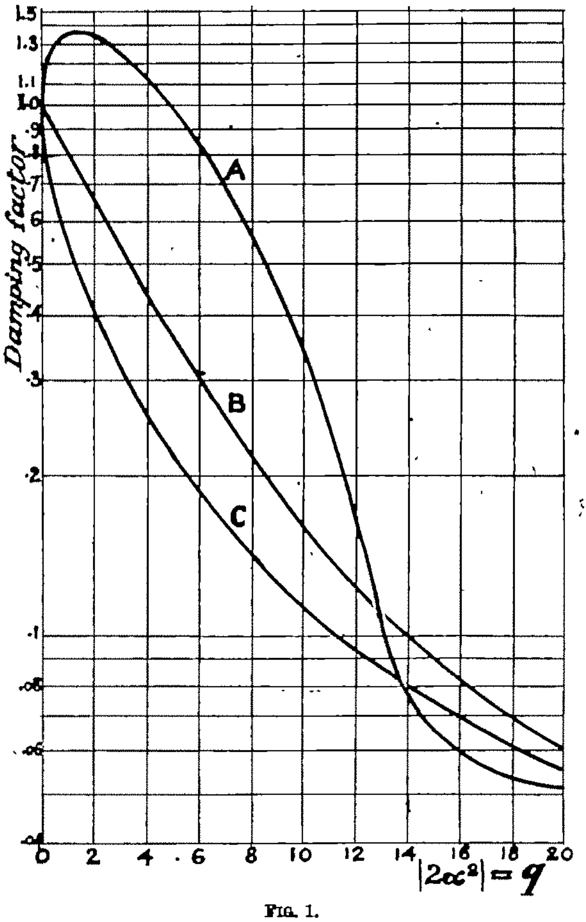

FIG. 1.

The computation of the damping is in this general case a trifle more tedious than when the soil is a pure conductance, but surely pays for the trouble taken. In the special case when $\cos b = \sin b = 1/\sqrt{2}$, *i.e.*, the capacity effect just as great as the conductivity effect, we have the damping curve *A* drawn in full in the accompanying diagram (Fig. 1); for comparison the trivial case of $\cos b = 1$, $\sin b = 0$ is also shown (B).

The former curve explains the very remarkable feature, first revealed by Mr. Barfield himself on the Daventry station, and amply confirmed by Mr. Lemoine on the Swedish stations at Karlsborg and Motala, namely, that the damping is *negative* for the first 20 or 30 kilometres. This is nothing but a feint on the part of the woods, which soon revenge themselves by an almost catastrophal damping farther away. It is a happy coincidence on certain wave-lengths that, in day-time, reflection sets in at the right moment to reinforce the vanishing direct ray. The same effect ought also to be shown by great expanses of fresh water, for example, the very pure water of Lakes Wetter and Wæner in Sweden, where the conductivity seems to be of the order 10^{-14} E.M.U.

The third curve drawn (C) is a by-product from the computations obtained by reversing the sign of *b*. This should be equivalent to introducing an inductive load, not improbably exerted by trees on waves shorter than their fundamental, thus explaining the very rapid decay of such waves when early entering a wood.

As the composite damping on the longer broadcasting wave-lengths is shown to be inversely proportional to something between the first and the second power of the wave-length, the Washington Conference of 1927 has seriously hampered the attempts to build up a broadcasting service in densely wooded and sparsely inhabited countries such as Sweden, by forbidding the use for this purpose of waves longer than 1850 m. No doubt this clause will be amended in the near future. In Sweden 'wood' means nothing less than some 40,000 trees per square kilometre!

It seems not improbable that a thorough investigation of the properties of various wave-lengths might result in better knowledge, and consequently better legislation.

A Dogfish without Pelvic Girdle or Fins.

A specimen of *Scyllium canicula* was noted, amongst a number of dogfish received from Plymouth, in which the pelvic fins were entirely absent and the sex was consequently indeterminate externally.

This naturally raised the question as to whether the pelvic girdle was normally developed. Subsequent dissection showed that there was no trace of the girdle. The dissection also showed that the animal was a fully mature male with the internal urinogenital organs normally developed, but, correlated with the absence of pelvic fins, there was no trace of claspers.

The urinogenital papilla was situated somewhat nearer the vent than is usually the case.

Abdominal pores were present on each side of the cloaca, but they did not open internally to the cœlom.

Functional Differences between Left and Right Splanchnic Nerves.

Stimulation of the peripheral end of the divided right splanchnic nerve in the abdominal cavity has revealed several marked differences in the resultant effect upon the blood-pressure from the well-known results obtained by similar stimulation of the left nerve. If the right nerve be stimulated by successive stimuli of sufficient strength at frequent intervals, a rapid exhaustion of the nerve occurs. Using a rapidly interrupted current with the secondary coil 10 cm. from the primary and 2-volt accumulator, it is found that there is a rapid diminution in the pressor response, and after about four or five stimulations no further rise of blood-pressure can be elicited with the same strength of current.

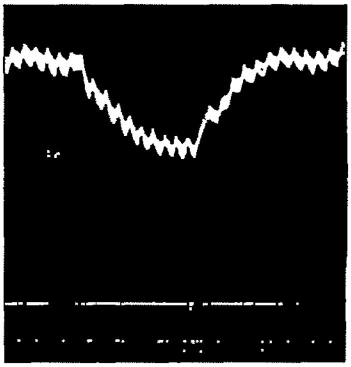

Fig. 1.—Mechanical stimulation of the peripheral end of the right splanchnic nerve by means of a glass rod producing a fall of blood-pressure. Time in 5 seconds.

I have obtained this effect with cats under various anæsthetics, and in the decerebrate and pithed conditions. Repeated attempts have failed to produce these results in the left nerve.

Coincident with the diminution of the rise of blood-pressure, a curious after rise becomes increasingly apparent. It occurs immediately after cessation of stimulation, and is very rapid in its formation. Ligature of the adrenal glands does not alter it, nor does ligature of the superior mesenteric or portal veins.

Continuation of the series of stimulations after exhaustion has taken place causes a *fall* of blood-pressure to be manifested, and eventually a condition is reached when even the strongest stimuli evoke falls of blood-pressure. The falls are most easily elicited by mechanical stimuli (Fig. 1).

Such results indicate that the right splanchnic nerve contains a considerable number of vaso-dilator fibres.

My thanks are due to Prof. Swale Vincent, without whose assistance and advice much of the work would have been impossible.

Dug-out Canoe in Algoa Bay.

The origin of the dug-out canoe, over which there was so much controversy, has now been finally settled. I have ascertained definitely that the canoes are in use in the East Indies, mostly at Celebes and the Malacca. At the latter place there are men who actually make them for sale.

The blocks with holes in them, at the sides of the canoe, are five in number. Three are for supports for plank seats on which the paddlers sit. The other two are for the purpose of securing the bamboos to which the outriggers are attached. The slot at the bottom of the canoe is for the insertion of the base of a pole for a sail.

Some Modes of Mechanical and Animal Locomotion.

By A. MALLOCK, F.R.S.

SUCH questions as how do birds fly, how do fish swim, how do ships steer, or snakes crawl, have been subjects of interest from very early times.[1] The present note is concerned with these and some other forms of locomotion, all of which may be placed under the heading of motion in fluids and motion on solids. Motion in fluids includes ships, airships, flying machines, birds, winged insects, fish, whales, and various swimming insects and Crustacea. Motion on solids refers to various legless creatures such as snakes, molluscs, and microscopic organisms.

MOTION IN FLUIDS.

A very general proposition applicable to all cases may be stated with regard to motion through a fluid; namely, if a body moves with a velocity v and experiences a resistance R, momentum is generated (either by pushing, pulling, or rubbing) in the direction of the motion such that $d(MV)/dt = R$. Here MV is an abbreviation for the integral of the mass of each element of fluid × velocity imposed on it by the progress of the body. If the source of power is contained in the moving body, an equal variation of momentum in the opposite direction must be generated in the fluid to overcome the resistance.

For the present purpose the source of power, whether screw, wing, paddle, or jet, may be called the accelerator, since its purpose is merely to accelerate the fluid in a direction opposed to R. The ideal accelerator may be taken as an area placed broadside to the stream, supplied with means of increasing the potential of the fluid passing through it, and experiencing therefore a reaction equal to the accelerating force. To determine what total flow and what velocity is required to produce a given reaction, let A be the area of the accelerator, v the velocity of the fluid, and ρ its density. The flow of mass is ρAv. If R is the given reaction and F the accelerative force acting on the fluid, and if $R = Mg$, then M is the mass of fluid which weighs R and occupies a volume Av. Thus $\rho AvF = Mg$. M is a constant, so that $F/g = 1$ and $A = \text{volume} \div v$. Take, for example, the case where the fluid is air and let $R = 1000$ lb. and $A = 1000$ ft.^{2}. A thousand lb. of air has a volume of about 12,800 cubic feet, and this volume per second will, starting from rest, acquire a velocity of 32 ft./sec. in passing through the accelerator when acted on by a force equal to its own weight. If the area is halved the velocity must be doubled and $F = 2g$, and so on.

The power required to produce the velocity is vR. In the diagram (Fig. 1), curves are given showing, in term of the area of the accelerator, the velocity of the air current necessary to cause a reaction of 1000 lb., and also the horse-power required to maintain it. A curve is added showing the diameter of the stream if the cross-section is a circle.

In this diagram it is assumed that the accelerator itself is stationary and that therefore all the work goes in creating currents in the air. If, however, the pressure drives the accelerator forward at a velocity v_2, then, in the absence of any acceleration, the flow of mass through the accelerator will be ρAv_2 per sec., and if v_1 is the velocity which must be added to this flow to maintain the reaction R, the power required will be $R(v_1 + v_2)$, and the requisite accelerating force will be less than that indicated in Fig. 1 in the ratio $v_1/(v_1 + v_2)$, *i.e.* a smaller force acting at a higher spead on a greater mass.

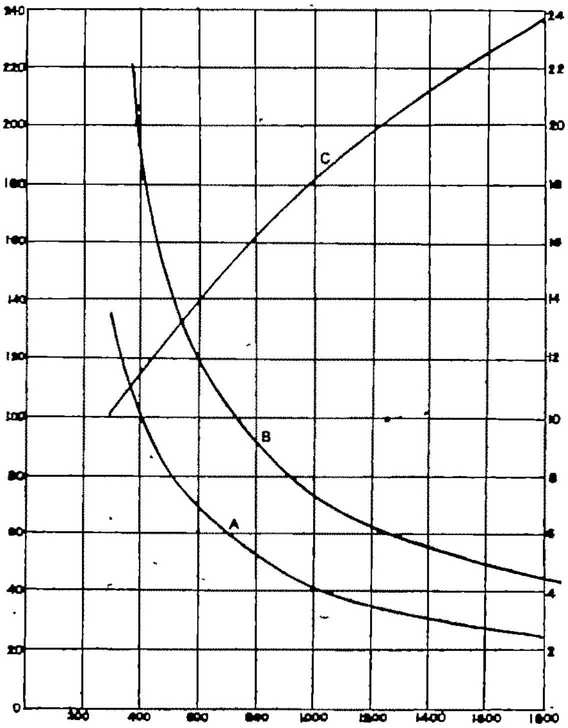

FIG. 1.—Curve A. Ordinates show the velocity in ft./sec. which must be given per sec. to a volume of air weighing 1000 lb. (in terms of the area over which the volume extends) in order that the reaction against acceleration should be 1000 lb. Curve B. Horse-power required to maintain the stream. Curve C. Radius of a cylinder of the same section area as that of the stream.

A somewhat similar case is that of a barge being poled along at a speed v_1 against a resistance R. If the bottom of the canal is hard and the pole does not slip, the bargee walks aft at the speed v_1 and does useful work at the rate v_1R. If, however, the pole slips at the speed v_2, he has to walk at the rate of $v_1 + v_2$, expending power $R(v_1 + v_2)$, of which Rv_2 is wasted.

For bodies the weight of which is borne by the fluid (such as airships, fish, etc.), the stream emitted by the accelerator is in the direction of the fluid resistance, but for flying machines, birds, and winged creatures in general, whose weight has to be supported dynamically, the stream must have a downward momentum component Mv_y, giving $d(Mv_y)/dt = W$, while the horizontal component Mv_x makes $d(Mv_x)/dt = R$.

---

[1] See Proverbs xxx. 18, and Epistle of James iii. 4.

In flying machines, the horizontal component, corresponding to R, is supplied by a screw, and the weight is supported by the inclined surface of the wing. With flying animals, however, the wings have to propel and also to support the body.

Fig. 2 shows diagrammatically the attitude of the wing during one complete beat. The propulsion effect is dependent on the change of wing angle during the up-and-down stroke, and is similar to the propulsion in sculling with a single oar. The weight is supported by the downward current induced by the curved wing section.

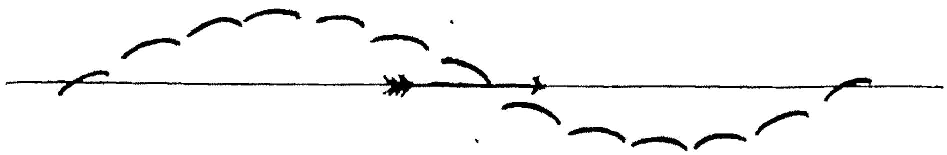

FIG. 2.—Diagram showing the attitude of the wings of a bird during one complete beat.

When a plane surface moves in a fluid, making an angle α with x (the direction of motion), it experiences a resistance R and a lateral force L in a direction y. L/R varies with α and has a maximum value of about 10 when the fluid is air or water. If the wing, instead of being a plane, is suitably curved and convex on the upper surface, the ratio L/R may approach 20. The reason for the approximate doubling of the lift is indicated in Fig. 3. The flow of the stream past the plane surface is as in (*a*), and past the curved surface as in (*b*), from which it may be seen that the downward component of momentum is nearly doubled in the latter. I need not here refer to the dynamics of these two forms of flow, on which there has been much discussion.

Birds which soar with their wings stationary make use in general of ascending air currents, though it is possible, as was shown by the late Lord Rayleigh, that when the velocity of the wind is different at different levels, they may soar by passing alternately into strata of quicker and slower wind speeds, provided that the speed gradient is sufficiently steep. I do not know, however, of any observations proving that this method is actually used. Ascending currents are formed in many ways, such as by the ascent of heated air, or by the configuration of the ground or waves on a water surface. With their long experience, birds have probably learnt to make use of any conditions which give the desired result.

Dr. Hankin, in India, made many observations on the soaring of birds, and found that none of the birds on the plains began to soar until the sun had risen for some time, and I myself have noticed that, on a hilly tropical island, soaring does not begin until the sea breeze has been established. From this it seems probable that ascending currents are the chief agents in soaring flight.

Hovering, that is, keeping the body stationary in still air by the working of the wings, is only found in Nature in small birds and insects. The heaviest bird which I have known to hover is our English kingfisher, but humming-birds are the typical vertebrate hoverers. More striking examples are to be found amongst insects, such as hawk-moths and hover-flies, but the best of all is a dipterous fly (Bombylius), like a small humble-bee, which when feeding on a flower will insert and withdraw its proboscis as steadily as if it were controlled by a fine adjustment screw.

The kestrel hawk has the power of keeping its position for short intervals with wonderful exactness. This, however, is not true hovering, but merely flying against the wind at the speed of the wind. In all true hovering the attitude of the body is nearly vertical, and the mean plane of motion of the wings approaches the horizontal.

The limitation of the size of hovering animals is, as may be gathered from Fig. 1, the small power to weight ratio in muscular action. From the diagram also it may be seen how futile it is to attempt to construct hovering machines, using as accelerators screws of size common in aeroplanes.

If inventors or designers could develop a machine which, with 1000 lb. total weight, could carry a 100 h.p. engine with an accelerator of any kind of an effective area of 600 ft. to 1200 ft. (which in the form of a screw would imply a diameter of 40 ft. to 60 ft.), a hovering machine would become a possibility.

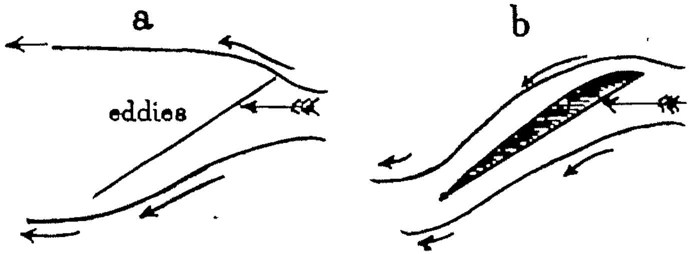

FIG 3 —Flow of fluid (*a*) past a plane surface placed obliquely in a stream, (*b*) past a surface plane on the upstream surface but with a convex back.

There are many examples in Nature of the use of oars and paddles. The chief paddlers are the swimming and diving birds with webbed or partially webbed feet. The general action of paddling is indicated in Fig. 4, which shows the position of the foot and the opening and closing of the toes during one complete stroke. When referred to a fixed point in the body, the foot describes a nearly circular path, and the successive positions of the web are not unlike those of floats in a feathering paddle-wheel.

The contrast between acceleration by paddles and wings may be well observed at the Zoological

Gardens when the diving birds are fed, for the penguin uses its short wings to fly under water, and I think that anyone would give the prize for speed and manœuvring power to the wings.

It is worth noting that these under-water wings, not having to support the weight of the bird (and therefore not having to give a downward component to the fluid on which they act), are nearly plane surfaces, and not, as in the case of air wings, convex on top.

The most familiar examples of the use of natural oars are found in the Dytiscous family and in the water-boatmen (Notonecta). Here one pair of legs greatly exceeds the other in length, and the last joints are bordered by a row of stiff bristles which stand vertically up and down during the backward or propelling stroke, but collapse in a horizontal plane as the leg is moved forward, thus in effect forming an oar which feathers under water.

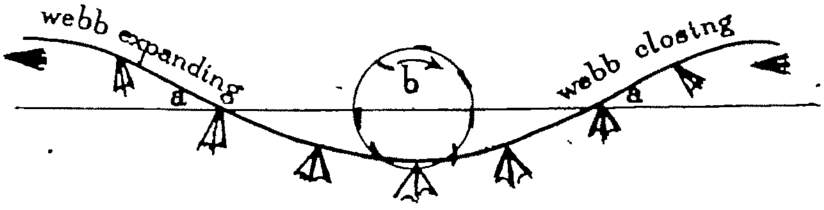

FIG. 4.—Diagram showing the action and position of the webbed feet of a swimming bird (*a*) with reference to a fixed point (*b*) with reference to the body of the bird.

Another and very curious example is found in the Gyrinidæ beetles. Here the tarsi are expanded into long paddle-shaped blades capable, when not in use, of folding within an enlarged upper joint. See illustrations *a*, *b*, *c* in Fig. 5. I do not know whether these blades are used as oars or as wings, but it would be possible, and certainly interesting, to take moving photographs of their action with the lens focused on the underside of the water surface.

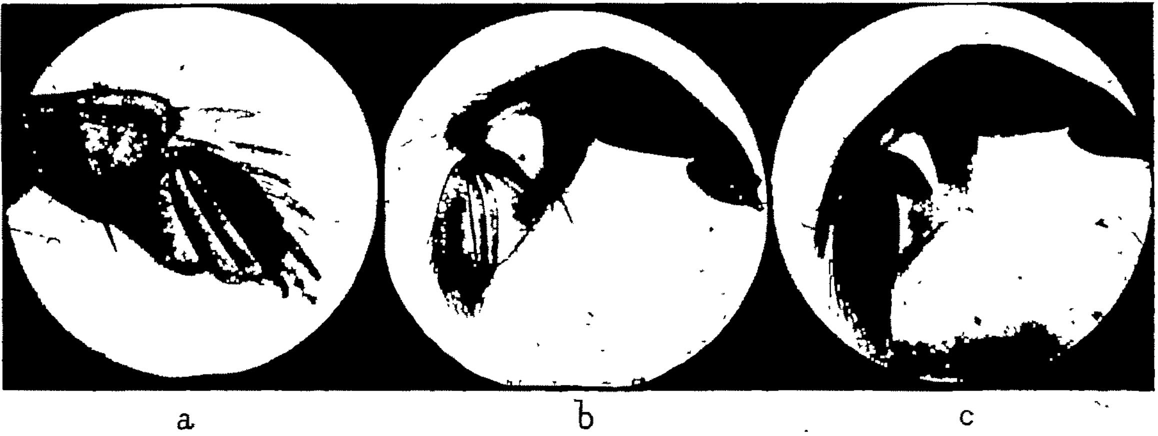

FIG. 5.—Swimming legs of Gyrinus, showing paddle-shaped tarsi (*a*) fully extended, (*b*), (*c*) partly closed.

In upright-swimming fish and whales the accelerator is the tail fin or flukes, and to some extent the tail end of the body, the action being that of sculling with a single oar. The greater part bulk and weight of both these classes consists of the muscles working the accelerators. The outstanding difference in the mechanism in Pisces and Cetaceæ is that in the first the muscular action bends the spine into a curve alternating to the right and left, while in the latter similar motions are caused up and down (Fig. 6).

Flat fish (soles, etc.) have two modes of progression: one for moving slowly in contact with the ground, the other being kept for quicker travel. In these fish the dorsal and anal fins are greatly developed, extending from head to tail. For slow movement these fins are bent into a waved surface (Fig. 7), the waves, with the water between the fins and the ground, travelling in a backward direction.

When higher speeds are desired the body is raised from the ground and the main series of muscles, which are connected with the spine and ribs, act in the same way as in the upright-swimming fish, but the flexure of the spine is now up and down, instead of from side to side.

Among the rays the ribs are almost wanting, and the whole width of the body is occupied by the greatly developed pectoral fins. The fin-rays are very numerous, and each of these is connected with a muscle rather similar in form to the muscles which in other fish are attached to the ribs.

I have had no opportunity to observe the way in which the rays use their pectorals, but it seems likely that it is similar to the action of the dorsal and ventral fins in flat-fish.

Flying-fish when submerged swim as the other upright-swimming fish, and must for a short time at least be able to travel very fast, for I have seen them rise close to the side of a ship going 15 knots and pass ahead at perhaps 4 or 5 knots faster. While in the air the pectoral fins act as glides only, as may be shown by the small size of their muscular attachments, but where the water is smooth they can prolong their flight by sculling with the tail fin, keeping its lower half in the water, so that the weight is supported by the air and the propulsion given by the sea. It is interesting to notice the increase in the speed of the fish after the tail is immersed.

The steering of ships, especially those with small rudders, is not completely explained by the action of the stream on an oblique rudder surface.

The course of an even perfectly symmetrical ship is unstable if not steered, since the centre of fluid pressure is in advance of the centre of inertia. In consequence of this instability, the wake tends to make an angle with the line of the keel, and thus to exert a turning movement on the ship. Even a small rudder, however, is sufficient to determine the direction of the instability, that is, whether the wake shall deviate to port or starboard, and a large part of the efficiency of the helm is dependent on this cause.

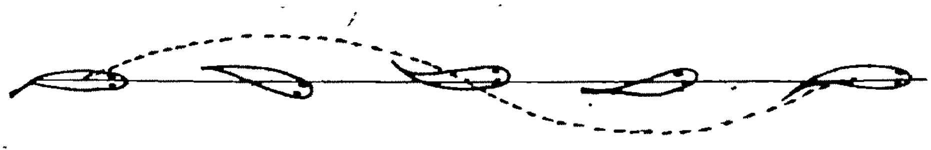

Fig. 6.—Showing the position of tail fin of an upright-swimming fish during one complete cycle.

The unstable wake gave a great deal of trouble in some of our earlier warships, and there was a class of small gunboats (meant originally, I believe, for service in the Chinese rivers) which were notorious for their erratic steering. There was a story of a captain of the *Excellent* entering Portsmouth Harbour on one of them being hailed by the master of a sailing barge beating out with: "Now, sir, if you will tell me what part of the harbour you want to get to, I'll try to squeeze into the rest."

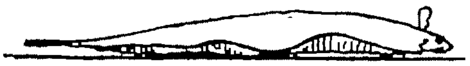

Fig. 7.—Showing wave-like form given to the dorsal and anal fins of flat-fish when moving slowly.

The manner of the progress of snakes has been much misrepresented. In Prof. Owen's "Anatomy of Vertebrates" there is a figure of a snake in the attitude of a looper caterpillar, like a Greek Ω. It has been said also that a snake 'walks' on the ends of its ribs; also it has been stated that it can, without any curvature of the body, move in a straight course by the ratchet-like action of the large ventral scales.

So far as my own observation goes, a snake on a flat smooth surface is in a very helpless condition, and can only progress by slightly raising the curved body on the right and left sides of the course alternately and straightening the raised portions. The track left by a snake in crossing a dusty road looks like a succession of horse-shoe marks such as are represented in Fig. 8. If there are any projections on the surface—grass, sticks, stones, branches, or in fact anything against which the body can get a 'purchase'—the snake bends itself into a curve to fit one or more of the projections and causes the curve to travel backward along the body, so that, with reference to the projections, the curve remains stationary and the body passes through the shape (Fig. 9).

The coefficient of friction between the body and the projection is involved in this, and here no doubt the edges of the scales on the under surface are of use in preventing backward slip.

The crawling of molluscs has not, I think, ever been satisfactorily explained, and I can only contribute two observations which bear on the subject.

(1) Having harnessed a large *Helix aperta* by a silk thread to a spiral spring, I found that it could pull about two and a half times its own weight before the foot began to slip on the surface on which it was crawling.

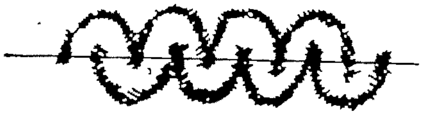

Fig. 8.—Track of a snake on a flat dusty surface.

(2) Taking young specimens of the same snail, which are translucent, and examining the foot by transmitted light, it was seen that, so long as the animal was in motion, dark waves were passing in a forward direction through the substance of the extended foot. There were two or three of these waves visible at the same time. Whether they indicate muscular contraction or regulate the secretion of mucous remains to be determined.

That there is some periodicity in the secretion of mucous is proved by the intermittent tracks with which snails mark garden walks, leaving patches of mucous separated by clear ground. The intervals between the marks are very constant so long as the character of the ground does not change.

On dry ground more mucous has to be expended, and where there is dust it is not uncommon to find a snail has died from exhaustion. On a dusty road having on one side a drying ditch and on the other a wet one, I once saw the tracks of a number of young Limax which had tried to cross. Not one had succeeded. The tracks, in parallel lines a few inches apart, extended from 6 inches to 2 feet over the dust,—a dead snail at the end of each.

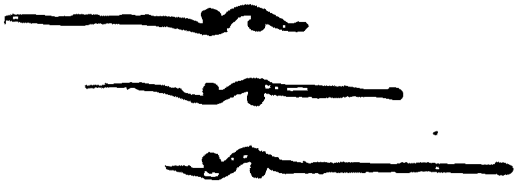

Fig. 9.—Showing mode of progression of a snake.

Many microscopic forms of life are capable of moving slowly by the action of cilia. The action of cilia seems to be that each individual hair is capable of extension and retraction as well as of lateral bending, and that in the extended state the extremities are all moving in the same direction, thus causing a flow of fluid over, or giving motion to, the ciliated surface when in contact with a fixed body, an action which is not unlike that of the fire-bars in an automatic grate.

I know of no explanation of the mechanism by which the cilia are actuated or of the conditions which determine their periodicity.

Nova Pictoris as a Double Star.

A RECENT note in our astronomical column stated that observations in January at La Plata and Johannesburg showed that Nova Pictoris was surrounded by a nebulous ring. About Mar. 26 the La Plata observers noted that the appearance of this ring had altered; they telegraphed to Johannesburg, asking for an examination to be made with the 26-inch refractor; this was done, and revealed the fact that the star appeared double.

A Reuter telegram on Mar. 28 added that the position angle was 70°, the components were about equal in magnitude, that each was nebulous, and that the distance between their centres was half a second. It was added that separation of two stellar points at this distance would have been easy, and that under the actual conditions a darker band could be detected between the nebulous discs. On the other hand, Dr. Spencer Jones, His Majesty's Astronomer at the Cape, in a statement quoted in the *Times* for Mar. 29, gives the distance between the stars as one-fifth of a second. The Johannesburg estimate is probably to be preferred, the telescope there being larger, and the observers having much practice in measuring difficult binaries.

Dr. Spencer Jones adopts the view that the outburst was due to an actual collision of two stars, which have now drawn apart sufficiently to enable them to be seen separately; this is the theory that Mr. Bickerton has advocated for the last forty years, but most astronomers have decided that there are far too many Novæ for this explanation to be tenable in general. It would be expected to happen only once in many million years. Nova Pictoris, however, differed in several respects from the average Nova, so the possibility of a collision need not be immediately dismissed; an opportunity will be afforded to test the suggestion when measures of the pair have been taken for some months. The rate of angular separation would not be uniform; it would slow down owing to the mutual gravitation of the stars, which would pass each other on hyperbolic paths.

There is, in any case, one important difference from Bickerton's theory; he postulated the formation of a third body between the stars, which would be for some time more luminous than them; but the Johannesburg telegram mentions a darker region in the middle.

Harvard College Bulletin 852, published in November last, quotes Mr. Davidovich's spectroscopic parallax 0·006″ (giving a distance of 540 light-years) and derives a proper motion of −0·042″ in R.A. (great circle) and −0·018″ in declination. This is from comparison of old plates with recent ones, both taken with the 24-inch Bruce refractor, the time-interval being 24·2 years. The original magnitude of the star was 13 (absolute magnitude 7); if there were two stars on the old plates, their images would probably be blended. The above motions give position angle 247°, which is very nearly in line with the angle 70° now reported.

The outburst occurred on May 25, 1925, so th the interval up to the detection of duplicity 2 years 10 months; assuming that the stars wer then together, this gives 0·18″ as the average annual rate of separation; but it would have been much more rapid at first, and would now have sunk to perhaps a third of this, so that a trustworthy measure of the rate cannot be expected for several months.

The occurrence is unprecedented in the history of Novæ, and is of great interest; the similarit of the two stars in magnitude and appea leaves little doubt that they are at the at distance from us, and that the phenomenon is is to be explained by the motion of the Nova reve ing an independent star that previously w hidden in its rays.

Obituary.

Mr. E. W. Maunder.

THE death of Mr. Edward Walter Maunder on Mar. 21, at seventy-six years of age, will be regretted by astronomers in many parts of the world. Mr. Maunder was for many years a member of the staff of the Royal Observatory, Greenwich, and his appointment indicated the beginning of the change in the character of that establishment that has occurred in the last half-century. In his report, read on June 1, 1872, the Astronomer Royal, Airy, put to the Board of Visitors the proposition that a continued series of observations of the solar spots, and perhaps some solar spectroscopic work, of which he spoke with less certainty, might fitly be undertaken at Greenwich, though the Observatory would then become *pro tanto* a physical observatory, and hinted that its operations might be extended in that direction in the future. This resulted in the appointment of Maunder as photographic and spectroscopic assistant on Nov. 6, 1873, and in the first half of the following year a spectroscope by Browning was attached to the 12¾-inch equatorially mounted telescope, then known as the Great Equatorial, and a photo-heliograph that had been used at Kew was installed in the Observatory grounds, both of which were given into Maunder's charge.

Thus began the forty-year series of photographs of the sun that was made under his direction. The first decade of the period was before the general use of the gelatine dry-plate, and the task of taking photographs by the collodion process daily, as weather permitted, was somewhat arduous. Maunder was partly relieved of this by the appointment of a skilled helper, and was able to devote some time by day to spectroscopic examination of the chromosphere and prominences, whilst at night the instrument was used for measuring the displacement of lines to determine velocities in the line of sight, occasionally for mapping the spectra of planets and stars, or, sometimes the telescope was used without the spectroscope for visual examination of, or for micrometric work on, the planets. Notes on the spectra of two Novæ, with others on similar subjects, are to be found in the *Monthly Notices of the Royal Astronomical Society* under Maunder's name, and for the most part the observations here mentioned are in the volumes of that publication. After the accession of Christie to the office of Astronomer Royal, the work of photographing and recording the sunspots was developed in several ways. The photo-heliograph was adapted so that (from April 4, 1884) the solar image had a diameter of 8 inches instead of 4 as hitherto, and the Greenwich photographs were supplemented by others taken at Dehra Dun and elsewhere to make the series complete.

This naturally made more demand on Maunder's time, and the personnel of the department was increased, but about the time of the sunspot maximum of 1894, the spectroscopic work at Greenwich was given up that he might devote himself wholly to the sunspots. The record of their positions and areas was kept by him with care and skill until his retirement in November 1913, and beyond the bare record, his ingenious tabulations and diagrams are of much value. A re-determination of the position of the sun's axis, published in 1912 and 1913, and a diagram showing the distribution of spots in latitude during three or more cycles, known as the 'Butterfly' diagram, may be mentioned, but his papers that received most attention were those on the association of terrestrial magnetic disturbance with the appearance of sunspots. A diagram in the *Monthly Notices* of November 1904, which displayed the solar longitude of the centre of the disc that was contemporaneous with the occurrence of magnetic disturbances in the years 1882 to 1903, showed unmistakably that magnetic storms are of solar origin. The idea of a short period in magnetic phenomena was not new, but it is doubtful whether it had been before exhibited so vividly.

It does not belittle Maunder's actual astronomical work to say that his greatest service to the science was the founding of the British Astronomical Association. In his early years at Greenwich he had formed a large circle of astronomical acquaintances, and in the year 1890 he was led to conceive the idea of an Association of amateur astronomers for mutual help, who because of their sex, or by other circumstances, might be precluded from joining the Royal Astronomical Society. Mainly by his efforts such an Association was formed, and the position of the organisation to-day, with its roll of a thousand members, many of whom are contributing observations of unique character and importance to astronomy, testifies to its success.

Maunder went abroad on six occasions to observe a total solar eclipse—twice as a member of a British official expedition; once as a guest of the Canadian Government, and three times he was a member of a party organised by the British Astronomical Association On four of these occasions he was favoured with fine weather.

Maunder had a ready pen, considerable command of language, and wrote much. He was acting editor of the *Observatory* magazine from 1881 until 1887. At one period he contributed the Astronomical Column to this journal, and at another did similar office for the now defunct *Knowledge*. He edited the *Journal of the British Astronomical Association* from its foundation until the end of the fourth volume, and from 1896 until 1900; and the complete series contains many articles by him on topics of varied nature, archaic astronomy being one of them. His book, "Astronomy without a Telescope," has found many readers, as has his "History of the Royal Observatory," whilst his elucidation of certain scriptural passages in his work "Astronomy of the Bible" elicited commendation from ecclesiastics in high position, the book itself being in keeping with the devoutness that was a marked feature of his character.

Maunder was twice married. His first wife died in 1888, leaving a family of three sons and two daughters, who survive him. In 1895 he married Miss A. S. D. Russell, who was formerly on the staff of the Royal Observatory, and is not unknown in the astronomical world. He joined the Royal Astronomical Society in 1875, and was a member of its council for several years, serving as honorary secretary from 1892 until 1897. He retired from his post at the Royal Observatory at the end of the year 1913, but was recalled during the years of the War to carry on the sunspot record.

Prof. Theodor Curtius, emeritus professor of chemistry in the University of Heidelberg, died at Heidelberg on Feb. 9 in his seventy-first year. Curtius, who was well known as the discoverer of hydrazine, hydrazoic acid and the azides, discovered also the method of obtaining aliphatic diazo-compounds. Lead azide, which he first prepared, soon became an important substitute for mercury fulminate as a detonator.

We regret to announce the following deaths:

The Right Hon. Viscount Cave, G.C.M.G., who had just resigned from the office of Lord High Chancellor, and Chancellor of the University of Oxford since 1925, on Mar. 29, aged seventy-two years.

Dr. William C. L. Eglin, vice-president of the Philadelphia Electric Company and president of the Franklin Institute, on Feb. 7, aged fifty-eight years.

News and Views.

In September next an important meeting of the International Illumination Commission, which was formed in 1900 and includes both the gas and electrical interests, is to be held in America. The objects of the Commission are the study of all subjects bearing on illumination and its cognate sciences, and the establishment of international agreements in illumination matters. There are at present National Illumination Committees in Austria, Belgium, France, Germany, Great Britain, Holland, Italy, Japan, Switzerland, and the United States of America. For the first time in the history of the Commission, a British president has been elected, namely, Mr. C. C. Paterson, Director of the Research Laboratories of the General Electric Co., Wembley. The Commission has already established an international standard of light, and is now dealing with such subjects as definitions and symbols, factory and school lighting, automobile headlights, heterochromatic photometry, photometric accuracy, fundamental research on glare, colorimetry. The British National Illumination Committee, which is closely associated with the Sectional Illumination Committee of the British Engineering Standards Association, the membership being practically identical, will be responsible for nominating delegates to represent the British viewpoint and British interests, and is anxious to secure adequate representation at these meetings. It is hoped that the delegates will include representatives of the Government departments, municipalities, the National Physical Laboratory, the electrical industry, the gas industry, and the principal associations interested in illumination matters. Mr. Buckley, of the National Physical Laboratory, Teddington, who is the secretary of the British National Illumination Committee, will gladly furnish full particulars.

The Report on Scenery-Preservation for 1926–27, issued by the Department of Lands and Survey, New Zealand, makes pleasant reading. Among many interesting reservations recently added is the Te Koru Pa in the Taranaki District. The pa, which was at one time the headquarters of the Ngamahanga Hapu of the Taranaki Tribe, is situated in a horse-shoe bend of the Oakura River, and, apart from its historic interest, has long been held in high regard as a favourite picnicking-ground. It forms one of the very few remaining examples of a pa with stone-faced glacis or parapets surrounding the tiki or citadel. The narrow neck connecting the pa with the mainland was in the old days defended by a very deep trench backed by three terraces, all of which were faced with stone to a height of 15 feet in places. This area was a gift to the Crown from the native owners. Mr. Wilkinson's report on Kapiti Island, which is in his care, contains much that will appeal to the naturalist. For example, he writes: "Nearly all over, or at least in places where the forest-roof is open, the *Uncinia riparia* is becoming a pest and is a menace to bird-life. . . . Not only does it hold small birds, but even the morepork is not able to extricate himself when once he is properly caught. The unfortunate part about it is that the plant is seeding, and therefore in its dangerous stage, just when the young birds are beginning to fly about. I have several times rescued birds, and in nearly every case they were adult birds, so that young birds caught must eventually die of starvation or be taken by the wekas."

The Report also notes the improvements effected by an Amending Act of 1926. This gives permission for the destruction of certain troublesome animals under stringent provisions. Power is conferred on local authorities to contribute towards the cost of acquiring scenic reserves and towards their improvement and maintenance. So far as possible, the control of reservations is vested in local authorities or special boards, and honorary inspectors are appointed. This affords enthusiasts an opportunity of performing useful service of value to the State, and encourages among the general public a regard for natural beauty. In England we have to protect our downs from the seaside bungalow. In our antipodes, "The advent of the seaside dwelling in the Sounds has proved an important factor in the improvement to the scenery during the past few years. Most of the owners of these are enthusiastic nature-lovers, and, besides protecting the remnants of native bush on their properties, have extended these by planting more native or introduced trees. In this way many hundreds of acres which a few years ago were in bracken or burnt bush are rapidly becoming reafforested, and prove a welcome addition to our efforts in conserving what we can of the original native bush that beautified the Sounds."

The Ministry of Agriculture and Fisheries has issued a statement of the measures taken to prevent the introduction into Great Britain of foot-and-mouth disease from South America. Epidemics of this disease have been traced to carcases imported from Europe, and the research committee investigating the subject has determined that the virus, if present, remains active in frozen carcases for 76 days. Negotiations were conducted with the Governments of Argentina, Brazil, and Uruguay, and the Ministry's Senior Veterinary Inspector, Mr. J. L. Frood, visited those countries and conferred with the officials there. Finally, Lord Bledisloe agreed to undertake a mission to the three countries to modify, if necessary, and to ratify agreements awaiting final approval. Agreement was reached respecting the measures necessary to prevent the importation of the foot-and-mouth disease virus with the frozen meat which comes from the three countries named. The tv principal clauses institute veterinary inspection the animals before removal from the *estancias*, ar of the animals at the freezing establishments before and after slaughter, with isolation of herds in the event of symptoms of contagious disease appearing among them.

The Folkestone Natural History Society, which was founded on April 4, 1868, has been celebrating its diamond jubilee. On Saturday, Mar. 24, a visit was paid to Snowdown College. At a public meeting held on the following Wednesday, short addresses were delivered by Mr. A. H. Ullyett on the history of the Society, by Dr. Walcot Gibson, on the value of local natural history societies, and by Mr. C. A. B. Garrett, on natural history in schools. During the evening especial attention was directed to the part the Society has played in the inception of the excellent Town Museum now under the able curatorship of Captain Moody-Foster. Occasion was also taken to present a set of silver-plate to Mr George Chapman Walton, in recognition of his long services to the Society as honorary secretary and as president—an office which he has filled since 1905. A lecture by Prof. Julian Huxley on the progress of biological science during the past sixty years, delivered on Friday evening; and a conversazione with exhibits and demonstrations, held on Saturday, Mar. 31, terminated a very successful anniversary of one of the oldest natural history societies in Great Britain.

A MEETING for the discussion of geophysical surveying was held at the Institution of Civil Engineers on Mar. 28, under the chairmanship of Sir John Flett, Director of the Geological Survey of Great Britain. The chairman, in his introductory remarks, emphasised the value of geophysical methods in the study of geology and mining, and indicated that the results recently obtained by the Geological Survey have proved entirely satisfactory. Dr. W. E. P. M'Clintock described a survey with the Oertling torsion balance over the Swynnerton Dyke in Staffordshire, by the Geological Survey, and showed the closeness with which the position of the intrusive dyke had been located and its features investigated. Not merely could the limits of the dyke be established, but also it was shown that the dyke was inclined slightly to the vertical. He stressed the convenience of the Oertling protecting hut, and the general convenience and portability of the apparatus. Mr. E. Lancaster-Jones outlined the evolution of a new instrument recently constructed for the measurement of gravity gradients. This instrument, termed a 'gradiometer,' is unaffected by curvature, and may be readily transported by one man. In speed of operation it is a considerable advance on previous instruments, and it should enable both reconnaissance and detail gravity surveying to be effected with greatly increased economy and efficiency. An account of field work with this instrument was given by Captain H. Shaw, who showed results that have been obtained in tidal areas. In one case an important fault showed up prominently, and was located with accuracy and interpreted in detail. In a second area, a noticeable subterranean feature was revealed, and by means of a dense station network it was possible to delimit this anomaly, and to give a complete interpretation of its characteristics. The sensibility and reliability of the instrument were shown to be quite up to standard, while the resulting gravity gradients were unusually consistent, and conformed completely to those previously obtained in adjacent areas. Captain W. H. Fordham spoke on the magnetometer and its applications to geology and mining, and described a new type of magnetometer recently produced by Messrs. Oertling Ltd., on the lines of the earlier Thomson-Thalen instrument.

SEMI-DESTRUCTIVE earthquakes occurred in north-eastern Italy near Udine (about 40 miles north-west of Trieste) on Mar. 26 and 27. The later and more violent shock was recorded at Kew at 8 hr. 34 min. 56 sec. A.M. (G.M.T.); the other at 2 hr. 43 min. 1 sec. P.M. The district visited by them is one in which earthquakes are of moderate strength and frequency. About 50 miles west of Udine is Belluno, a small town that almost coincided with the epicentre of the strong earthquake of June 29, 1873. This earthquake was studied by Prof. H. Hofer (Wein, *Ak. Sber.*, vol. 76, pt. 1, 1877, pp. 819-856) and is probably the first attributed to an origin in two distinct foci. Hofer suggested that two faults were then in action simultaneously, one running south-east, the other east, from a point near Belluno. The latter, as traced by him, passes close to Udine and Tolmezzo, places at which much of the damage caused by the recent earthquakes occurred. A further earthquake, described as violent, was recorded at Kew Observatory on Mar. 31 at 0 hr. 35 min. 2 sec. G.M.T. The epicentre is estimated to have been 1620 miles away, probably between Greece and Crete. The disturbance recorded at Kew was considerably more violent than that produced by the recent earthquake in the Italian Alps.

BY the provisions of an enactment about to be introduced in the Federal Council of the Federated Malay States, it will be made an offence to take fire-arms or other apparatus for killing animals or birds into a game sanctuary or reserve. Game rangers will be given power to seize animals, birds, trophies, or fire-arms, etc., which have been used in the commission of an offence. A notification in the *Federated Malay States Government Gazette* announces that rewards for the destruction of 'noxious animals' will be paid on the following scale: Tigers, full grown, 25 dollars each, cubs, 10 dollars each; leopards, full grown, 15 dollars each, cubs, 5 dollars each; crocodiles, up to 2 feet in length, 25 cents each, more than 2 feet long, 3 cents an inch; crocodiles' eggs, 25 cents each; hamadryads and cobras, 5 cents per foot. Claimants for rewards are required to produce the carcase or fresh skin in the case of tigers or leopards; in the case of a crocodile, the unbroken vertebral column will suffice.

THE Perkin Medal was instituted by the Society of Dyers and Colourists in commemoration of Sir William Perkin, who died in 1907 during his presidency of the Society. It is awarded at intervals of two or three years for discoveries of outstanding importance in connexion with the tinctorial arts. Previous recipients of the medal have been Profs. Graebe and Liebermann, for their synthesis of alizarin (1908); Prof. Adolf von Baeyer, for his synthesis of indigo (1911); Comte Hilaire de Chardonnet, for his pioneer work on artificial silk (1914); Prof. A. G. Green, for his discovery of primuline (1917); M. R. Vidal, for his work on sulphur black (1919); Mr. H. Lowe, for his work on the production of permanent lustre on cotton (1921); Mr. C. F. Cross, for his discovery of viscose (1923); and M. M. Prud'homme, for his work on aniline black and alizarin blue (1925). At the annual dinner of the Society, held in Manchester on Mar. 23, the Perkin Medal was presented to Dr. R. E. Schmidt, of Elberfeld, for his remarkable work on anthraquinone and allied bodies, which has led to the discovery and commercial production of a whole series of fast dyestuffs. The medal, which was struck in gold, was modelled by the late F. W. Pomeroy, R.A., and is an excellent presentation of Perkin's head in profile.

The protection from lightning flashes of petroleum tanks, which are often assembled over a large area, is a problem of considerable importance. The flames arising from burning oil often reach great heights, and in some cases the burning oil can only be prevented from spreading over the adjoining land by digging up trenches round the blazing area. In the *Electrical Review* for Mar. 9, a method is described which has been installed in America for protecting such areas. Colonel Wilcox claims that it secures absolute immunity. Steel towers are connected round the area and are connected at the top by a ring of wires in a horizontal plane. When the atmosphere is electrified, brush discharges take place from points on this ring. This undoubtedly minimises the danger. We agree with Sir Oliver Lodge, however, in thinking that it fails to give absolute protection. There is no reason why a flash of the 'impulsive rush' or *B* type should not strike an object inside the ring. The experiments carried out in America on a small model of this protective device produced only *A* flashes, and in this case almost absolute protection would be secured. St. Paul's Cathedral in London is protected by a horizontal loop encircling the dome and by other conductors. Six-point aigrettes are jointed at intervals to the loop and similar aigrettes are used at Westminster Abbey. K. Hedges, who designed both systems, recognises the powerful effects of points in levelling down excessive stresses, but he does not claim that they give absolute protection. The accident at Tunbridge Explosive Works in 1918, when hermetically sealed drums of nitro-glycerine were detonated, although the lightning conductors were of the most modern type and in excellent condition, proves how difficult it is to guard against a *B* flash.

The decision of the eastern associated submarine cable companies to co-operate with Marconi's Wireless Telegraph Co., Ltd., in developing 'world-radio' is a wise one. They have successfully overcome many difficulties during the last eighty years, but the rapid development of the beam system of radio and possible competition in world-radio by foreign companies at last induced them to see that co-operation was the wisest policy. The recent Imperial conference of representatives of the Dominions discussed the question of cable-radio, and both the cable companies and Marconi's gave evidence, but so far the discussions at the conference have been kept secret. Until the Imperial government has notified its decisions, the Marconi-eastern combination is handicapped by not knowing what powerful interests will have to be considered and consulted. In the *Electrician* for Mar. 23, R. Belfort lays stress on this aspect of the problem. He points out that the virtual arbitrators of the situation may themselves be formidable competitors, as they can own and exploit both cable and radio enterprises. The Americans also have a vast organisation of radio, telephone, and cable companies which are continually developing their methods and extending their operations. It seems probable that the Commercial Cable Co. of America will soon possess a complete round-the-world cable-radio service. A similar girdling of the earth will probably also soon be accomplished by the Western Union Telegraph Co. Those and other competitive developments make it difficult to prophecy how profitable the new enterprise will be. America occupies a fortunate position, as its communication companies are all under private control. Mr. Belfort thinks that just as the Eastern company was unable to resist Marconi competition, so it is possible that a Marconi-Eastern combination may not be strong enough to confront American and other foreign competition. In our opinion, however, the improved service will increase the revenues, and this increase should be sufficient to satisfy the legitimate claims of all the competitors.

By the Protection of Lapwings Act, 1928, which received the Royal Assent on Mar. 28, and is now in force, the sale, or possession for sale, for human consumption of lapwings' eggs and also of the bird itself between Mar. 1 and Aug. 31 in each year, is absolutely prohibited. The Act applies equally to native and to imported eggs and birds.

The Gold Medal of the Institution of Mining and Metallurgy has been awarded to the Right Hon. Sir Alfred Mond, "in recognition of his scientific and industrial services in the development of the mineral resources and metallurgical industries of the British Empire." The Medal will be presented to Sir Alfred Mond at the annual general meeting of the Institution to be held at Burlington House on Thursday, May 17.

The Council of the Royal Anthropological Institute has awarded the Huxley Memorial Medal for 1929 to Baron Erland Nordenskiöld of Goteborg. He has also been invited to deliver the Huxley Memorial Lecture in November of that year. Baron Nordenskiöld's researches in the archæology and ethnology of South America hold a deservedly high place in the estimation of anthropologists, and the award will be welcomed as a merited recognition of many years' valuable work.

It was announced in the House of Lords on Mar. 29 that a committee of inquiry had been set up to inquire into the possible danger arising from the use of lead tetra-ethyl in motor spirit, composed as follows: Sir Frederick Willis (chairman), Sir George Buchanan, Dr. Bridge, Mr. Pye, Sir Charles Martin, Sir Robert Robertson, Major Galwey, Dr. C. H. Lander, Prof.

A. C. Chapman, Sir William Willcox, and Prof. Dixon. The secretary to the committee is Mr S. F. S. Hearder, Ministry of Health, Whitehall, S.W.1, to whom all communications should be addressed.

Friday evening discourses after Easter at the Royal Institution include: "Heirlooms of Industry in the Science Museum," by Sir Henry Lyons; "Carriers of Electricity in the Atmosphere," by Prof. A. M. Tyndall; "Life's Unsuspected Partnerships," by Prof. Doris L Mackinnon; "Engine Knock and Related Problems," by Mr A. C. Egerton; "The Results of the further Excavations at Ur," by Mr. C Leonard Woolley; and "The Waves of an Electron," by Prof. George P. Thomson.

Applications are invited for the following appointments, on or before the dates mentioned:—Temporary assistant quantity surveyors and temporary architectural draughtsmen under the Mines Department——The Under-Secretary for Mines, Establishment Branch, Mines Department, Dean Stanley Street, S.W.1 (April 14). An assistant pathologist in the Laboratories of Pathology and Public Health, 6 Harley Street, W.1—The Secretary (April 20). A teacher of engineering subjects at the Cheltenham Technical School—The Secretary, County Education Office, Shire Hall, Gloucester (April 20). A lecturer in electrical and mechanical engineering at the Forest of Dean Mining School, Cinderford—The Secretary, County Education Office, Shire Hall, Gloucester (April 20). A secretary to the delegacy of the University of London for co-operation with Training Colleges in the London District in accordance with a Scheme approved by the Board of Education—The Principal Officer, University of London, South Kensington, S W 7 (April 21). A test assistant in the Chemical Department of the Royal Aircraft Establishment — A.273, Chief Superintendent, R A.E., South Farnborough, Hants. A head of the Mechanical and Structural Engineering Department of the Borough Polytechnic Institute—The Principal, Borough Polytechnic Institute, S.E.1.

Our Astronomical Column.

The Recent Transit of Mercury.—*Circular No.* 75 of the Union Observatory, Johannesburg, contains a discussion of the observations of this phenomenon made at several observatories. In the mean, the phases were 23 seconds earlier than the predicted times, as compared with 30 seconds in 1924. It will be remembered that the lunar errors are also slightly diminishing. The view is now largely held that these fluctuations indicate variability in the earth's rate of rotation, the periods of the oscillations being somewhat irregular, but considerable fractions of a century. Dr. Benjamin Boss (*Daily Science News Bulletin*, Science Service, Washington, Feb. 28) suggests that there are in addition fluctuations of much shorter period (days or hours) in the rate of rotation; he thus explains the puzzling anomalies found in the meridian determinations of time and Right Ascension at most observatories. He suggests as an explanation that the solid surface of the earth, when raised by lunar and solar tides, may not completely settle back, but remain raised for some time, and then at last reach a breaking point and return abruptly. Such settling back would sometimes reach the magnitude of an earthquake, and in fact Dr. Boss notes that his time variations show relationships with the frequency of earthquakes.

Stellar Parallaxes from Allegheny Observatory.—The excellence of the numerous parallax determinations made at this observatory is well known, and regret will be felt that the latest instalment (*Yale University Transactions*, vol. 6, Pts. 1 and 2) is the last with which Prof. Schlesinger will be personally concerned. There are three stars of special interest in the list. The parallax found for Barnard's star of record proper motion is 0·550″. It is noted that this is the best determined stellar parallax, the mean of seven good determinations being 0·538″. For ε Hydræ the value found is 0·026″, in good agreement with 0·025″, found spectroscopically from the radial velocities of the close components. Betelgeuse is interesting from the large angular diameter given by the interferometer. The value found for its parallax is 0·013″: the trigonometrical determinations range from 0·011″ (Mount Wilson) to 0·024″ (Yale heliometer) The mean of seven spectroscopic determinations is 0·011″; but the spectroscopic scale must be a little uncertain for such extreme giant stars, the means of graduation being restricted. The well-known binary 70 Ophiuchi has a parallax of 0·184″. The probable errors of these parallaxes are about 0·01″ or less.

The Spectra of Comets.—Several important papers on this subject have appeared recently, including discussions by N. T. Bobrovnikoff, of various Yerkes photographs taken during the period 1908–1927 (*Astrophysical Journal*, vol. 66, pp. 145 and 479). The first of these treats of Halley's Comet in considerable detail. The spectra were studied photometrically with a self-registering microphotometer and compared with direct photographs. A variation in size and brightness of the principal monochromatic images of the head indicates the development of the CN and C + H, rather than the Swan, bands as the comet recedes. Two types of continuous spectrum were discovered—one due to reflected sunlight, and the other the comet's own spectrum with a maximum intensity at λ4000. The existence of the latter depends on the comet's heliocentric distance, only appearing at distances greater than 1·2 astronomical units.

The second paper deals with the spectra of 22 comets, all of which resemble Halley's in the above respects and in the existence of sudden changes in their spectra. The change from solar to cometary type of continuous spectrum takes place usually at a distance of about 0·7 astronomical units from the sun Bredichin's theory of cometary tails is not supported by these observations, and fluorescence is suggested as a probable origin of cometary spectra.

A third paper on comets comes from Meudon, by M. F. Baldet (*Annales de l'Obs d'Astr. de Paris*, tome 7). In this paper a historical survey is given of our present knowledge of the subject, with various tables of wave-lengths which should be of considerable value in the identification of cometary lines. Detailed discussions follow of the spectra of eight comets, and of laboratory researches into the spectra of relevant sources. It is to be regretted that the author does not always follow the recommendations of the International Astronomical Union in the printing of his photographs.

Research Items.

AVOKAIYA FISHING.—In *Man* for March, Mr. E. E. Evans-Pritchard, who has visited the Moro tribes of Mongalla Province on behalf of the Sudan Government and with the financial assistance of the Royal Society and the Laura Spelman Rockefeller Trust, describes the interesting methods of dry-season pool-fishing employed by the Avokaiya tribes. They use fish scoops made in a few minutes from millet stalks, tied together with cords of fibre. The mode of procedure is as follows: a line of boys is formed across the pool or stream, who draw the scoops all together across the pool or push them in front of their bodies. When the end of the pool is reached the boys form a semi-circle around the bank. When the number is insufficient to form a continuous line, they cover the distance as best they can, and small boys swim and splash on the open side of the pool. Small boys also swim about to frighten fish into the scoops, while the boys at the end of the line feel under the banks with the same object. Simple as the process looks from the bank, it is more difficult than it seems, as is shown by the difference in the catch when experienced fishers take part. A great deal depends upon the celerity with which the mouth of the scoop is closed when a fish has entered. Both the Avokaiya and the Moro are agricultural peoples, and the fish form a welcome addition to the food supply. The mode of fishing here described seems to be more of a play activity than a method of economic utility. The Moro Meza use fish poisons, but the Moro Kodo also use nets and large hand-worked hooks.

INDIA AND THE PACIFIC.—In the *Ceylon Journal of Science*, vol. 1, pt. 4, Mr. A. M. Hocart publishes some supplementary notes on his studies of the Indian and Fijian caste systems. He now states that in addition to the absence of the fourth caste in Fiji, the absence of the third caste in Samoa is to be noted. The power is divided or contested between the nobles and the masters of ceremonies, just as a tendency in this direction is to be observed in India, where traditions show the Vaisyas dropping into obscurity and the aristocracy resolving itself into two rival castes, Brahmins and Kshatriya. India retains, however, the fourth unitiated caste, whereas the Samoans have assimilated their fourth caste to the nobility. The existence of the four-caste system is preserved in the history of the Four Brothers of Upolu, who each went out to seek a country for himself and his people. When they divided up their possessions, Sana received the staff and fly-whisk, the insignia of the public orator or master of ceremonies, the spear and club were given to Ana, the digging stick with which yams are planted to Tua, but Tolufale received nothing. The fact that the orator is mentioned first may have a bearing upon the question whether the original position of the Kshatriya was first as is generally assumed. In both India and Samoa and Tonga, a nobleman may be a priest. In Samoa and Tonga chiefs may assume the orator's title if they have an ancestress of that caste. It is also suggested that the Indian barber caste may have to be identified with the caste known in Fiji as *mbouta*, who are exempt from the consequences which follow when anyone touches the sacred body, and especially the head, of the chief. Epithets employed of them suggest they may be of noble descent or a clan of noble bastards. The Indian barbers may in the same way be derived from priests, *i.e.* descendants of a Brahmin father and a Sudra mother.

RUSSIAN ZOOLOGICAL STUDIES.—The *Annuaire du Musée Zoologique*, Leningrad, which has been very late in appearing, is now coming out very regularly, three parts of the vol. 27 and one of the vol. 28 having been published during 1927. These publications contain a very long series of zoological papers on different groups. P. Schmidt gives revisions of two genera of fishes, Icelus and Gymnacanthus, while B. Iljin published a critical list of Gobiidæ of the Black Sea. On mammals there are papers by B. Vinogradov (on the mechanism of gnawing and mastication in some burrowing rodents); Flerov, on mammals of the Tchorokh district in Transcaucasia, and on a new subspecies of *Ochotona hyperborea* from the Polar Ural; M. K. Serebrennikov describes the fauna of rodents of the Samara province, and S. S. Ognev gives a description of a new genus and species of cat (*Eremaelurus thinobius* Ogn.) from Transcaspia. On birds there is only one paper, by B. Stegmann, on birds of the Alai steppes, but there is also a paper by C. A. Kurova on trematodes of the family Echinostomatidæ from birds in Turkestan. Papers on invertebrates include, to mention only a few, a list of Acarina of the Kamtchatka, by S. Thor; revision of two genera of Polychæta, by N. Annenkova; a list of the Orthoptera of Crimea, by E. Miram; descriptions of Solifugidæ from Africa, by A. Birula; list of Hydroidea and Alcyonaria from the Barents Sea, etc.

THE MAY-FLIES OF INDIA.—The study of May-flies is so little advanced in tropical regions that a description of the material contained in the Indian Museum and other Eastern institutions is especially welcome. In *Records of the Indian Museum*, vol. 29 (1927), Dr. B. Chopra provides the first part of a general account of the Indian species and their biology; this contribution, which occupies pp. 91-138, is illustrated with three finely executed plates. In his prefatory remarks on the wing venation, the author points out that the homologies of certain of the veins are still far from definitely established, and he provides a useful tabular comparison of the various systems of nomenclature that have been advocated. In view of the present position of the subject, the Comstock-Needham system is followed, and it has the advantage of having been more widely adopted than the schemes that have aimed at emending it. In the general classification of May-flies the work of Ulmer has been adopted almost completely, and in the present contribution certain of those species falling in the group Ephemeroidea are discussed and, where necessary, described at length. Of the new species discovered, one belongs to the genus Palingenia and two to Polymitarcys.

MODIFICATION OF DEVELOPMENT BY TEMPERATURE GRADIENTS.—Prof. Julian Huxley (*Roux Arch. f. Entwick. der Organ.*, Bd. 112, pp. 480-516) has subjected frog's eggs and embryos and chick embryos to temperature gradients in various directions (*a*) with the main axial gradient of the organism and thus adjuvant, (*b*) against the main axial gradient and thus antagonistic, and (*c*) lateral to the main axial gradient. The results seem to show that, during segmentation, at the higher end of the temperature gradient, division of cells is accelerated, with the result that adjuvant gradients accentuate the normal size differences between animal and vegetative cells, while antagonistic gradients diminish them. These alterations in segmentation have little effect on subsequent development. Lateral gradients applied to frog embryos in the neural plate to tail-bud stages produce marked asymmetries which, however, do not always persist in subsequent development. Lateral gradients applied to chick embryos produce acceleration of development of the heated side with marked increase in the tissues and in the size of organs on that side. Antagonistic gradients applied to chick embryos cause enlargement of the primitive streak posteriorly, retardation of brain development, reduction in the head size in the later embryos, and precocious development of the hind limb buds. Adjuvant gradients produce opposite results on head size and limb bud development.

Nematode Spermatogenesis.—N. A. Cobb (*Jour. Washington Acad. Sci.*, 18, No. 2, Jan. 1928) records observations on spermatogenesis in a free-living nematode, *Spirina parasitifera*, common an inch or two deep in sand between tide marks on both sides of the North Atlantic. Four spermatids are formed from a spermatocyte, but instead of metamorphosing into spermatozoa, each spermatid undergoes further changes and divisions and gives rise to a 'spermatidian tissue' of 64 and finally 128 cells. The male passes the spermatidian tissues into the uteri of the female. Fertilisation is preceded by an increase in size of that cell of the spermatidian tissue adjacent to the ovum next to be fertilised; this spermatidian cell is transformed into a 'spermule,' which fertilises the ovum. Whether every one of the 128 spermatidian cells metamorphose in this way is as yet undetermined. The author says that he knows of a large number of other species of nematodes belonging to numerous and varied genera in which the general appearances in the gonad of the male so closely resemble those described as to leave no doubt that their spermatogenesis follows a similar course.

Form Variations of the British Freshwater Pearl Mussel.—H. H. Bloomer gives an account of the variation of the British and Irish forms of *Margaritifera margaritifera* in *Proc. Malac. Soc. Lond.*, vol. 17. 'Form' in this paper is defined as "the external shape of the shell when observed from a lateral point of view without any regard to the shape of the teeth, muscular impressions, or other internal characters." Twelve different 'forms' are figured on photographic plates, including one from the River Wye which presents "a general conformity with certain characters which seem to justify making it a new local variety," var. *siluriana*. Local distribution is discussed river by river, and brief diagnoses of the dimensions and appearance of the contained pearl shells given.

Traverse Methods.—The United States Coast and Geodetic Survey has issued as *Special Publication No. 137*, a small manual of first order traverse which, in spite of its slender bulk, is a useful summary of the methods employed in traverse work in the American surveys. Field methods and office computation are both covered. The manual is a useful companion volume to that on first order triangulation recently published.

Periodicities in the Nile Floods.—From a long series of Nile flood records, extending from A.D. 641 to 1451, taken from the original Coptic records and corrected to the modern calendar, Dr. C. E. P. Brooks has investigated the question of periodicity and gives his results in a paper in the *Memoirs of the Royal Meteorological Society*, vol. 2, No. 12. The method employed for analysing the data is that known as the difference-periodogram. The result was the discovery of 19 periodicities of lengths varying from 1·91 to 76·8 years, some of them well established and others of doubtful validity. Some of these periodicities bear a simple relation to one another, as the series 5·52, 11·06, 22·12, 33·49, 66·0, 76·8 years. In fact, eleven of the periodicities agree within 1 per cent. with a simple multiple or sub-multiple of 22·12 years. One of the remaining periodicities could not be determined accurately, but another has a discrepancy of so much as 3·5 per cent. A few of these periodicities fit with those recorded from other data, especially the 33·49, which agrees fairly well with the variable Brückner periods. The more difficult task of finding a cycle of variation in the length of the periodicities led to no conclusive results, but there were indications of a 500-year period.

The Outer Shells of the Earth.—A stimulating discussion by Prof. R. A. Daly of recent evidence bearing on the structure of the lithosphere appears in the *Amer. Jour. Sci.*, Feb. 1928. The disagreement between the results of A. Mohorovičić, Gutenberg, and Jeffreys on the thickness of the sial of the continents is pointed out, and it is shown that owing to the absence of any generally accepted solution, there is still uncertainty as to wave velocities at different depths in the crust. It is thought that, under the low stress conditions of seismic waves, the rocks may have higher effective elastic moduli than under the high pressure conditions of laboratory investigations. Corroboration of this idea is found in an analysis of the hysteresis curves of Adams and Coker. Thus the data of seismology do not as yet forbid belief in a basaltic substratum. It is thought that the velocities of earthquake waves in holocrystalline basalt and glassy basalt would be nearly identical at the contact, and therefore that the latter, if it exist, will be difficult to detect. Thus the substratum below a certain depth may be rigid but glassy. The postulate of an earth shell of peridotite *near* the crust is considered to be both unnecessary and unjustified by evidence. A new interpretation of the intermediate layer is offered. Jeffreys regards this as tachylyte and Holmes as diorite and quartz-diorite. Daly suggests that it may represent a quartz-bearing rock at a temperature beyond the transition point of α-quartz to β-quartz (575° C.). The sudden change of elastic properties at the inversion temperature indicates that Daly's view has much to commend it.

Thunderstorms as Sources of High Potentials.—In *Forschungen und Fortschritte*, of Feb. 20, there is an interesting article by A. Brasch, F. Lange, and C. Urban on a project for obtaining extremely high potential differences, for use in such experiments as Rutherford's on atomic disintegration, from thunderstorms. It is estimated that within practicable heights above the earth's surface, of a few hundred metres, there are available at times potential differences of 5-30 million volts. For this purpose a cable 660 metres long has been stretched across a valley near Lugano, carrying, near its middle point, 80 metres above the ground, a collecting network. Details are given of the arrangements for insulation of the cable and for the measurement of the potential differences. Preliminary measurements made during the only suitable thunderstorm which occurred during the period of observation indicated a potential difference of above one million volts, causing a spark across an air gap more than 4 metres long.

Magnetic Theory.—In volume 4, No. 4, of the *Proceedings of the Imperial Academy* of Japan for 1928, Prof. K. Honda puts forward in a short paper a new theory of the origin of magnetism based on the structure of the atom. In present theories, magnetic properties are attributed to the outer electrons of the atoms, but Prof. Honda attributes diamagnetism only to these electrons, his explanation of the property being along the usual lines. Para- and ferro-magnetism he attributes to the nuclear electrons, which revolve in the nucleus with speeds approaching that of light, and produce magnetic moments of the requisite magnitude. In order to endow this atom with the power of turning towards a magnetic field, he supposes that a certain number of the protons revolve in the opposite direction to the electrons. In ferro-magnetic substances the angular momentum of the nucleus is supposed small, so that a magnetic field easily turns them, while in paramagnetic substances the momentum is great. According to the author, a quantitative examination of the theory leads to the explanation of many observed facts in magnetism.

TOTAL REFLECTION OF ELECTRONS.—An interesting suggestion has been made by O. Klemperer, in the *Zeitschrift fur Physik* of Feb. 24, to the effect that electrons, which are known to act under appropriate conditions as if they were diffracted, can also be totally reflected. If a particle entering a solid from a vacuum is retarded, the speed of its associated phase wave must be increased, when the corresponding index of refraction becomes less than unity, and for sufficiently oblique incidence, penetration of the surface cannot take place. This idea receives a certain amount of support from some experiments that were done several years ago on the secondary emission of electrons from the surfaces of various bodies bombarded at different angles by homogeneous beams of primary electrons. For electrons which had been accelerated through a fall of potential of a few kilovolts, the retardation in glass and some other insulating substances was equivalent to between one and two kilovolts, and although this is admittedly higher than would be expected from thermionic and photo-electric phenomena, its value for metals is much smaller, and of the order of what is required to account for the apparent contraction of the spacing of the atomic planes in a crystal of nickel indicated by the diffraction experiments of Davisson and Germer.

ISOMORPHISM OF AMMONIUM AND PHOSPHONIUM HALIDES.—Although a tendency to isomorphism is evident between ammonium and phosphonium halides in which all the hydrogen atoms are replaced by alkyl radicles, for example, tetra-ethylammonium bromide and tetra-ethylphosphonium iodide, the absence of isomorphism among non-substituted ammonium and phosphonium salts has resulted in the view that the resemblance between the groups NH_4 and PH_4 was merely formal. In a paper published in the volume for 1927 of the *Rendiconti dell' Accademia delle Scienze e Matematiche* (Naples), Congilio and Caglioti show, however, that crystallisation of a solution containing ammonium and phosphonium iodides gives rise to mixed crystals of the ammonium iodide type, containing phosphonium iodide in proportions varying to a maximum of 1·92 per cent.

PREPARATION OF LEAD TETRA-ETHYL.—*Report No. 29, Aeronautical Research Institute, Tokyo Imperial University*, by T. Tanaka and T. Kuwata, contains a study of the preparation of lead tetra-ethyl from ethyl chloride, using Grignard's reaction. Lead tetra-ethyl was obtained by the action of lead chloride upon ethyl magnesium chloride below 5° C. The crude product was purified by treating the ethereal solution with oxygen in the presence of dilute hydrochloric acid until it was colourless and crystallising out the triethyl lead chloride present in the solution. The lead tetra-ethyl had an unpleasant odour and boiled at about 82° C. under 11 mm. pressure. It decomposed on heating to 400° C. and at ordinary temperatures became turbid on exposure to air and sunlight.

THE CO-ORDINATION VALENCY OF ALUMINIUM IN ITS SALICYLATO DERIVATIVES.—In its complex compounds, the co-ordination number of aluminium is either four as in the alkali aluminates, or six as in cryolite. The two stable hydrates which are apparently formed by aluminium oxide, may accordingly be regarded as $H[Al(OH)_4]$ and $H_3[Al(OH)_6]$. In one case aluminium resembles boron with a low co-ordination number, and in the other it shows its resemblance to iron and chromium. In the January number of the *Journal of the Chemical Society*, G. J. Burrows and I. W. Wark describe an investigation of the salicylato derivatives of alumium. Various derivatives of aluminosalicylic acid $H_2\left[(C_7H_4O_3)_2Al\begin{matrix}OH\\OH_2\end{matrix}\right]$ were prepared in which the co-ordination valency of aluminium is six, indicating, therefore, its resemblance to iron and chromium. An unsuccessful attempt was made to resolve the alkaloidal salts of the above acid into optical isomerides.

COMPLEX ETHYLENETHIOCARBAMIDO-SALTS OF UNIVALENT AND BIVALENT METALS.—Owing to the presence of two amino-radicals as well as a thiocarbonyl group, thiocarbamide forms polynuclear as well as mononuclear derivatives with metallic nitrates. The co-ordinating properties of the amino groups may, however, be inhibited by incorporating the two nitrogen atoms in a five-membered ring as in ethylenethiocarbamide,  $\begin{matrix}CH_2-NH\\ |\\ CH_2-NH\end{matrix}\!\!>C=S$, represented by *etu*. The preparation of a large number of the complexes formed between this compound and various metallic salts is described by G. T. Morgan and F. H. Burstall in the *Journal of the Chemical Society* for January. Each molecule of the base is considered to contribute two electrons from its sulphur atom to the co-ordination complex and, thus, in the compound $[Cu, 4\,etu]NO_3$ the cuprous ion acquires eight additional electrons, thereby becoming equivalent to the rubidium ion. Similarly, silver and cadmium complexes are electronically equivalent to cæsium and barium ions respectively. Such analogies are supported by the fact that these complex nitrates give rise to neutral solutions and by the electrical conductivities of these solutions.

AN ELECTRICAL INDICATOR FOR HIGH-SPEED ENGINES.—J. Obata and Y. Yosida describe in the *Reports of the Aeronautical Research Institute of the Imperial University of Tokyo* (No. 28, December 1927) an electrical indicator for high-speed engines which gives excellent results. The principal difference between this instrument and the usual mechanical or optical one lies in the use of a steel disc 2 mm. thick and 5 mm. in diameter. Compared with ordinary discs, its thickness is very great. The minute motions of this disc caused by the pressure in the cylinder are recorded by an exceedingly sensitive electrical method called the 'ultra-micrometer' method, which utilises a generating valve circuit. Using two small engines, several records of actual engine pressure were obtained by an Einthoven string galvanometer, a Lutz-Edelmann string electrometer and a Duddell oscillograph. The results show that this electrical indicator gives correct diagrams for high-speed engines for which ordinary indicators cannot be used. The calibration of the indicator was made statically, a standard pressure gauge of the Bourdon type and compressed air being used.

Scientific and Industrial Research.

Promotion and co-ordination of scientific research by the State on any widespread scale is still novelty enough to invest the recently published Report of the Committee of the Privy Council for Scientific and Industrial Research for 1926–27, accompanied by the Report of the Advisory Council for the same period, with a special degree of interest. To the reports are attached a summary of work conducted by the various research organisations functioning under the auspices of the Department, and appendices containing tabulated information of a statistical and bibliographical nature, together with references to the development of organised research in other parts of the Empire.

In addition to the work of the research associations, the activities of the National Physical Laboratory, the Geological Survey, the Fuel Research Station, the Building Research Station, and the Forest Products Laboratory are described, and much information is given concerning the progress of work on food storage and transport, water pollution, and chemotherapy. It is satisfactory that important investigations at the Low Temperature Research Station, which have been delayed for lack of funds, can now be proceeded with in view of the receipt of a substantial grant from the Empire Marketing Board. There is, however, still urgent need for a coastal station devoted to the study of the preservation of fish and the utilisation of fish by-products. The magnitude of some of the issues at stake can be adjudged by reference to work in progress demonstrating the successful conversion of coal into liquid fuels; it still remains to be seen whether the new industry will be firmly established before existing sources of petrol begin to fail. The Advisory Council makes some pertinent remarks on the conditions under which the Geological Survey and the Museum of Practical Geology are housed. It is earnestly to be hoped that the scheme for a new building, once authorised by Parliament but still suppressed on the grounds of economy, will soon be put into effect.

A glance at the summary of work in hand during the year demonstrates the great diversity of the interests involved. The study of chemical reactions at high pressures is being carried on both at the Chemical Research Laboratory, Teddington, and at the Imperial College of Science and Technology; the Aerodynamics Department has dealt with a very full programme, including tests of airship models and the elimination of wing-flutter, in the investigation of which mathematical analysis has afforded a large measure of success. Considerable progress has been made in fuel research, despite hindrance due to the stoppage in the coal industry. The keeping qualities of apples are believed to be concerned with the protoplasm content and the extent of the sugar reserves, and the possibility of a precise prediction of the duration of life of the fruit under any set of conditions by means of chemical examination at harvesting is predicted. Radio observations made during the solar eclipse are mentioned; ‘wireless’ enthusiasts will also be interested to note that differences in wave attenuation are attributed largely to the absorbing effect of trees, greatest attenuation being observed in the most densely wooded parts of the country, and that the large number of receiving aerials in the London area appears to have a considerable energy-absorbing effect. The number of specific problems submitted to the British Museum Laboratory tends to increase; the work specially referred to in the report includes the mounting, cleaning, and preservation of delicate materials, the identification of early porcelain, and the unrolling of brittle manuscripts on leather.

The report would have been incomplete without some reference to the work of the National Research Council of Canada, the Australian Commonwealth Council for Scientific and Industrial Research, and the New Zealand Department of Scientific and Industrial Research, to the activities of the South African Departments of Mines and Industries, Agriculture, and Forests, and to those of various Indian Departments.

Origin and Development of Portion of the Australian Flora.

In the second part of his presidential address before the Australasian Association for the Advancement of Science at Hobart, delivered on Jan. 16, Mr. R. H. Cambage discussed the “Origin and Development of Portion of the Australian Flora.” The position was summarised as follows:

There appear to be more genera common to Africa and the eastern half of Australia only, than to Africa and the western half of Australia only, so that evidence of a direct land connexion between these two countries is meagre.

It is thought that many genera which are common to Africa and Australia have reached these countries from the same source in the north, and have then developed in response to environment.

From available evidence it would seem that, at least since Cretaceous time, the northern hemisphere has had a greater land mass than the southern, and, as a result, there has been more room for plant development in the north than in the south. Probably the Pleistocene and even earlier glacial periods have been instrumental in permitting many genera to pulsate across the tropics from temperate northern regions, and in the process, and after arrival in the south, there have been much radiation, development, and evolution. Although there probably has been more migration to Australia from the north, there is evidence in some cases of secondary radiation from the south, especially in the genus Eucalyptus.

It seems undoubted that some genera common to Australia and New Zealand have reached both countries from the north, some species coming down the east coast of Australia, while others have gone by way of New Caledonia and adjoining islands to New Zealand.

Except for a land connexion between north-eastern Australia and islands to the north, perhaps so late as Pliocene time, Australia has long been isolated from the rest of the world.

There appears to be more evidence in favour of a former land connexion between Antarctica and South America, and perhaps New Zealand and Australia, than between Africa and Antarctica.

Studies of the many changes which have taken place in the history of the world's flora, of its adaptability to environment, its response to change of climate and soil, its ability to overcome many adverse conditions, all combine to impress one with the conviction that the marvellous act of creation not only embodied the initial giving of life, but also provided inherent power and initiative for the necessary development and evolution required for the persistence of that life, in harmony with its varying surroundings and dominating influences.

Past and Present Peoples of Chinese Turkestan.

AT a meeting of the Royal Anthropological Institute on Tuesday, Mar. 27, Sir Arthur Keith gave an account of a people who lived in the eastern part of Chinese Turkestan in the earlier centuries of our era. His account was based on five skulls which were obtained by Sir Aurel Stein during his third expedition (1913–15) to central Asia. The explorer found these skulls in sites within the eastern and southern fringe of the Taklamakan desert—sites now dried up and forsaken, but irrigable and inhabited when the Tarim basin of Chinese Turkestan formed part of the corridor along which in past times Chinese trade flowed towards the west.

The people from these ancient cemeteries show a mixture of characters, some of which are Mongoloid, others of which are Caucasoid (or Iranian), but on the whole the Mongoloid traits are the more evident. Amongst the Lopliks and other peoples still inhabiting the eastern and south-eastern fringes of the Tarim basin are found individuals which come very near to the Loulan type found in the ancient cemeteries. From data collected by Sir Aurel Stein and collated by Mr. T. A. Joyce, it is apparent now that the peoples at the eastern end of the Tarim basin—the floor of which is formed by the Taklamakan desert—are transitional in type. When traced towards the north and towards the east they rapidly become Mongolian; when traced along the south side of the Tarim basin towards the west the Iranian type prevails more and more and becomes pure when the Pamirs and the valley of the Oxus are reached. The Loulan people who lived in the eastern part of the Tarim basin more than 1500 years ago were of a transitional type. Sir Aurel Stein's discoveries show that the racial frontier between Mongolian and Caucasoid types in this part of the world has not greatly altered its position since the Christian era began. The Loulan people were probably true Huns.

Intermarriage and migration do take place across racial frontiers, and most anthropologists explain a mixed type, such as the Loulan, as a result of intercrossing. In Sir Arthur Keith's opinion such an explanation leaves the most important facts of the problem unexplained. We have, in the first place, to explain the origin of the primary types—the Mongoloid and Caucasoid. We have to explain the greatest racial divide in the world, one many thousand miles in length, which crosses the Old World and separates peoples of a Mongoloid type in the east and north from others of a Caucasoid type in the west and south. This divide is traceable from the north-west corner of Europe to beyond the mouth of the Ganges in Asia. The great divide crosses the Taklamakan from west to east; the Loulan people lived on it. We cannot explain the origin and distribution of peoples of Mongoloid stock and the existence of the great racial divide unless we presume that evolution is true and that the stocks which we find on one side of the divide and on the other have come into their present states of body and brain in the areas where we now find them. If, as we presume, Mongoloid and Caucasoid stocks have in the course of time become differentiated from a common type, then between the extreme forms there ought to be, or to have been, transitional types occupying intermediate zones. If evolution is true we ought to find intermediate types on frontier zones, and that is what we do find. In Sir Arthur Keith's opinion the Loulan people should be interpreted, not as products of hybridity, but as of a natural evolutionary process.

In unravelling the Mongoloid from peoples of Caucasoid affinities, head form is not decisive. Mongoloid peoples are of all degrees of long-headedness and of all degrees of round-headedness. So are Caucasoid peoples. The Loulan people, who had heads of medium size, were intermediate between long and round. As a rule the Mongoloid peoples of central Asia had the larger heads and brains; the Iranian peoples of the Pamirs were small headed and not big-brained. The main points which serve for the discrimination of Mongoloid peoples are hair, skin colour, and facial form. A considerable part of Sir Arthur Keith's paper was devoted to Mongolian characters of face and the methods which should be applied for their analysis and measurement. In conclusion, he thanked the Government of India for the benefits which have been conferred on science through the expeditions led by Sir Aurel Stein who, in Sir Arthur's opinion, has done more than anyone to clear up the racial constitution of the peoples of central Asia.

Water Movements in the Straits of Gibraltar.

PROF. RAPHAEL DE BUEN publishes an account of the oceanographical investigations which have been carried out by Spain in the Atlantic and Straits of Gibraltar, in the *Journal du Conseil International pour l'exploration de la mer*, vol. 2, No. 3, December 1927.

Periodic fluctuations in the depth at which particular temperatures occur have been noted by the *Dana* Expedition in 1921 and by the various Spanish expeditions in this area. They were attributed to tidal phenomena (NATURE, 109, 45; 1922), but Prof. de Buen goes a step further. Since the periodicity does not correspond with that of the Atlantic tide, he considers that they owe their origin to deep-seated Mediterranean tidal waves.

The author does not consider that a sub-surface current of Mediterranean water wells out into the Atlantic over the ridge between Gibraltar and the African continent, such as has been shown to take place by Danish and Norwegian oceanographers (*loc. cit.*).

Prof. de Buen writes: "It may be seen in all the series of observations made during the campaign of the *Almirante Lobo*, as also in my maps (published in the *Rapport Atlantique*, 1926), which are based on the observations made during the campaigns of the *Dana* and the *Thor*, that at no time do the Mediterranean waters penetrate to the Atlantic. This must not, however, be accepted as an established fact until further investigations have been carried out, having as their object to discover whether at any time, at the moment when the bottom waters approach most nearly to the surface, some quantity of Mediterranean water does not find its way into the Atlantic. The Mediterranean influence in the Atlantic was found in all the observations to be nil. It is therefore necessary to seek some other explanation of the existence of warm dense water to the south-west of Ireland, in which some experts have considered that they could see a markedly Mediterranean character."

Somewhat inconsistently, "the layer of Mediterranean water which penetrates into the Ocean through the Straits of Gibraltar" is cited a few pages later as a possible explanation of the migration of sardines in the neighbourhood of Cadiz.

University and Educational Intelligence.

LONDON.—Dr. W. W. Jameson has been appointed as from Jan. 1 to the University chair of public health tenable at the London School of Hygiene and Tropical Medicine. Dr. Jameson received his medical education at the University of Aberdeen, the Rotunda Hospital, Dublin, and University College, London. From 1914 until 1919 he was assistant and lecturer in the Department of Hygiene at University College, London, and since then he has been Medical Officer of Health of different London boroughs. In 1926 he was appointed lecturer on public health and preventive medicine at Guy's Hospital Medical School. He is the author of "A Synopsis of Hygiene" (Churchill), of which a second edition has been published, and of papers on public health matters.

Dr. E. E. Turner has been appointed as from Sept. 1 to the University readership in chemistry tenable at Bedford College. Dr. Turner was educated at Coopers' Company's School, London, at East London College (1910–14), and Sidney Sussex College, Cambridge (1916–19); he obtained the degree of D.Sc. (Lond.) in 1920. After holding posts at the Goldsmiths' College, London, and at the Technical College, Huddersfield, he worked during 1919–21 as lecturer in organic chemistry, University of Sydney. For the period 1921–23 he was chemist in the Research Department at the Royal Arsenal, Woolwich, and since 1923 has been senior lecturer in chemistry at East London College. He has published numerous papers independently and conjointly in *Proc. Roy. Soc.* and in the chemical journals.

The title of reader in physical chemistry in the University has been conferred on Dr. Samuel Sugden, in respect of the post held by him at Birkbeck College. Dr. Sugden studied at the Royal College of Science from 1912 until 1914. Later he became a research chemist in connexion with explosives in the Research Department of the Royal Arsenal, Woolwich. In 1924 he obtained the degree of D.Sc. (Lond.). He has been lecturer in chemistry at Birkbeck College since 1919. His published work includes papers on the determination of surface tension and its variation with temperature and some related functions, on the parachor and chemical constitution, and on molecular volumes at absolute zero, published in the *Journal of the Chemical Society*, and a translation of Stock's "Ultrastrukturchemie," under the title "The Structure of Atoms" (Methuen).

ST. ANDREWS.—A scholarship of £100, tenable for three or four years at the United College, St. Andrews, by a student who is resident in the University Residence Hall, has just been established by the gift of Dr. David Russell of Markinch. The new Russell Scholarship is available to candidates who have spent at least two years in a secondary school under the Fifeshire Education Authority, or whose parents or guardians are resident in Fifeshire, and preference will be given to a candidate from Markinch district.

THE Ramsay Memorial Fellowships Trustees will consider at the end of June applications for fellowships, one or more of which will be limited to candidates educated in Glasgow. The value of each fellowship is £250 annually, plus a grant for expenses. The fellowships are held normally for two years, but may be extended for a third year. Applications must be received by June 5 by the Secretary, Ramsay Memorial Fellowships Trust, University College, Gower Street, W.C.1.

THE Ministry of Agriculture and Fisheries is prepared to receive, up to May 15 next, applications for grants in aid of scientific investigations bearing on agriculture, to be carried on in connexion with a university, university college, or other approved institution or society in England and Wales during the academic year beginning Oct. 1, 1928. Particulars of the conditions on which these grants are offered are set out in form A.53/T.G., obtainable from the Secretary, Ministry of Agriculture and Fisheries, 10 Whitehall Place, S.W.1.

AN appeal for a capital sum of £50,000 for the extension of the Ramsay Laboratory of Chemical Engineering at University College, London, and for its equipment, was made recently by the Chemical Engineering Building and Equipment Fund Committee, of which Sir Alfred Mond is chairman. The response up to the present time has produced £23,555. Among the subscribers are: Imperial Chemical Industries, £10,000; The Shell Group, £5000; The Gas Light and Coke Company, £5000; Dunlop Rubber Company, £1000; Messrs. Reckitt and Sons, Ltd., £1000. In addition to the capital fund for the building and equipment, an income of £6000 a year is required for the maintenance of the Laboratory. Towards this £3191 has already been promised for the first five years and £2600 for the second five years. The Committee is anxious to complete both funds as speedily as possible in order that the new building may be proceeded with. Donations and subscriptions may be sent to Sir David Milne-Watson, at University College, London (Gower Street, W.C.1), who will be glad to supply any further particulars.

THE Royal Technical College, Glasgow, records in its report on the work of the session 1926–27 an increase from 4149 to 4169 in its total enrolment. This followed four sessions of decreasing numbers, reflecting the depressed condition of the engineering and shipbuilding, mining and metallurgical industries with which the College is closely connected. Of the 934 day students, 245 pursued degree or diploma courses, and 136 other day students attended twenty or more hours a week. University degrees, including one D.Sc. and three Ph.D., were obtained by 36 students. Experimental and research work carried out for local industrial firms, much of it having reference to problems arising out of the use of very high temperatures in steam engines, continued to grow. In the Department of Chemistry, a special laboratory was equipped for the use of the Scottish Coal Survey Committee, and the whole of the analytical work and most of the research in connexion with Scottish coals will henceforth be centred in the College buildings. With the aid of a grant from the Iron and Steel Institute much new apparatus was acquired. In the engineering laboratories a series of investigations on the creep of metals approached completion. The School of Navigation, now the largest of its kind in Great Britain, arranged a course of study for cadets serving on board ship. This pioneer effort in continuation class work for youths at sea attracted attention in other countries. The School of Pharmacy was recognised by the authorities concerned as providing complete facilities for candidates for the B.Pharm. degree of the University of London and the higher qualification of the Pharmaceutical Society of Great Britain.

ERRATUM.—The announcement of the appointment of Dr. J. C. Earl to be professor of organic chemistry in the University of Sydney in our issue of Mar. 31, p. 519, was placed incorrectly under St. Andrews. Dr. Earl is a graduate of St. Andrews, but has been lecturer in organic chemistry in the University of Sydney since 1922.

Calendar of Customs and Festivals.

April 8.

EASTER DAY: the greatest of the three great festivals of the Christian Church. It is generally agreed that it coincided with and replaced a pagan festival. Traces of such a festival are to be seen in both ecclesiastical and popular observance. The form of morning greeting, "Christ is risen," with the reply, "Christ is risen indeed," which was formerly the rule, and is still observed in the Greek Church, might be held to imply, in the light of other customs, the survival of a belief in a real and annually recurring resurrection, such as that which was the cardinal doctrine in the Eastern cults of Adonis and Attis.

A brief account of the observance of Easter among a modern peasant population serves to bring out the essential elements in the festival pointing to the survival of ideas belonging to an earlier stage of religious belief. In Macedonia the Resurrection is celebrated twice. The first occasion is at a midnight mass on Easter Eve, when the service begins in the open. When the Gospel of the day has been read and the hymn "Christ is risen" has been sung, Lent is considered to be over. Guns are fired amid shouting, the eggs and cakes which have been brought by the worshippers are eaten, and the priest lights a candle, calling upon the congregation to light their tapers from his candle. This they hasten to do. The church doors are then thrown open after a challenge and reply, and the congregation troops in to the service. The second mass takes place on Easter Day, when the worshippers repair to church, each with a lighted taper. After the service, general greetings and the reconciliation of any enmities take place before entering upon the three days' feast, in which the exchange of presents of eggs coloured red and the eating of lambs roasted whole are the principal features. The Paschal fire is kept alight during the whole of the Paschal week.

The representation of the Crucifixion by an image is a common feature in the Roman as well as the Greek Church, and in the southern parts of Europe it is a custom for this representation to be carried in procession on Good Friday. A period of general lamentation and mourning follows until Easter Day, when there is firing of guns and fireworks or a bonfire, and a feast of a lamb. Frazer notes the resemblance of this custom in particular to the mourning for the death of Adonis and the rejoicing at his resurrection. The parallelism with the death of Attis on the tree is, as he notes, also especially close.

Early churchwardens' accounts indicate that English practice, in addition to the Paschal candle, included a representation of the Crucifixion, and in one case a figure of Judas is mentioned.

LENTEN AND EASTER FIRES.—The ceremonial extinction of all lights in church on Easter Eve and rekindling them from the Paschal taper preserves the idea of purification which underlies the custom of kindling bonfires at Easter and at various other times during Lent, but especially on the First Sunday, which was widely spread among the European peasantry. The custom was purificatory and protective. The larger the fire, the wider the area over which it brought prosperity to the crops.

THE PASK EGG.—The custom of making presents of eggs, the symbol of new birth and fertility, is very widely distributed. It occurs in most European countries as well as in the East. The eggs are boiled, gaily coloured, though most frequently red, and otherwise ornamented, sometimes being covered with or made of silver. In Persia this use of the egg was associated with the feast of the vernal equinox. In Egypt it occurs among both Moslems and Copts, at the time of the Coptic Easter in both cases. The eggs are used in a game in the north of England which is also found in Egypt, in the Balkans, and elsewhere. The eggs are rolled or struck against one another, the conqueror, *i.e.* the egg which breaks another, counting up victories until vanquished in turn.

April 9.

EASTER CELEBRATIONS.—Reference has already been made to the feast of a roasted lamb which follows the Easter services. In England the great dish was a gammon with green herbs or a tansy pudding, *i.e.* a pudding of bitter herbs. There are frequent records of the distribution of doles such as the cakes impressed with the shape of two females at Biddenham in Kent, or the cake once cut up and distributed to children in Twickenham church on Easter Sunday. These may have a sacrificial character, for the cross bun or Easter cake was originally an offering or part of a sacrificial meal, as was the lamb.

EASTER MONDAY.—Of numerous observances, only the more significant can here be noted. It was the occasion for sports, or rather contests, especially with a ball. In the Early Church bishops used to sport at handball with the inferior clergy. The significance of such contests as marking the break between two seasons, such as winter and spring or summer, has already been noted. There is, however, a group of customs which, while not superficially related, when taken together appear to have a deeper significance. At Coleshill in Warwickshire young men tried to catch a hare, and if they brought it to the parson before ten o'clock, they were rewarded with a gift of a calf's head, a hundred eggs, and a groat. The hare is here a symbol of fertility. At Greenwich on Easter Monday girls used to roll down the hill. This is well known from a number of parallels as a fertility custom. In various parts of England and Wales, but especially in the north, the custom of heaving or lifting obtained. On Easter Monday the men used to lift the women, either on their arms or in a chair, and obtained a kiss or the forfeit of a shilling for their pains, while on the following day the women heaved the men. The custom of lifting or jumping is noted by Frazer as occurring among the European peasantry to promote the growth of the corn.

In Yorkshire and Durham on Easter Sunday or Monday the young men stole the buckles from the girls' shoes. On the following day the girls stole the buckles or the hats of the young men. The property was redeemable on the Wednesday by a small pecuniary forfeit to be spent on a tansy pudding. At Portaffery, in the north of Ireland, it was the custom for hundreds of young people to resort to a walk outside the town, when the men kissed the girls promiscuously without offence. Finally, in a Glamorgan custom, a burlesque meeting of men held on the Sunday and Monday was taboo to women. Any woman caught observing the proceedings was liable to lose her shoe, which was redeemed by a kiss, or, if a married woman, a small fine. Of these customs, some are obviously connected with fertility; others involving a rivalry of the sexes, the stealing of a shoe or shoe buckle, and kissing either as a right or a forfeit, suggest the sexual licence which among primitive peoples has been noted as characteristic of seasonal festivals and as a means of promoting fertility.

Societies and Academies.

London.

Linnean Society, Mar. 15.—**Stanley W. Kemp**: Whaling research and the work of the *Discovery* Expedition. The principal object of the *Discovery* Expedition is the study of whales and whaling in the southern hemisphere. The history of whaling in the north shows that species have been reduced, sometimes almost to the point of extinction, by methods far less deadly than those at present employed. Experience indicates that when once a stock of whales has been seriously depleted, recovery, if it is ever effected, is a matter of centuries, and it follows that, if too many rorquals are taken in the south, there is a grave risk that a very important source of wealth will be destroyed. The actual extermination of any species of whale, however, is most improbable under present conditions, for long before this point can be reached, commercial operations would cease to be profitable. The two ships of the expedition, the *Discovery* and the *William Scoresby*, have for the most part been engaged in research on the plankton and hydrography of southern waters with the view of obtaining precise information on the environment of whales. In the south, whale-food appears to consist exclusively of a single species of Euphausia (a crustacean related to the decapods), and a special study of this species and the reasons for its great abundance in certain parts of the Antarctic has been made. Hydrographic work, to determine the physical and chemical constitution of the water, has been undertaken in conjunction with the planktonic observations (see also Nature, Oct. 30, 1926, p. 628).—**P. J. Greenway**: The forest flora of south Central Africa. Much of the material was collected by Mr. R. Bourne, of the Imperial Forestry Institute, while on a tour of inspection on behalf of the Northern Rhodesian Government. The collection represents 131 species, comprised in 80 genera and 34 families. The three families of Leguminosæ furnish the largest number of species. Only two genera, Monotes and Marquesia, of the Dipterocarpaceæ, are met with; of the former there are several reputed specimens, which are fairly common in the dry savannah-forest. *Marquesia macroura* Gilg, the 'Musesjie,' is one of the most abundant trees in Northern Rhodesia and the Katanga, where it attains a height of 65 to 80 feet; the wood is described as very hard and of good quality, and is used for finishing houses and in carriage-building. Of especial interest is the occurrence of a species of Hirtella (Rosaceæ). This genus is chiefly American in its distribution, being represented by about 40 species in Central and South America.

Edinburgh.

Royal Society, Mar. 5.—**H. Graham Cannon**: On the feeding mechanism of the fairy shrimp, *Chirocephalus diaphanus*. Chirocephalus feeds on minute suspended particles. Water is sucked in between the limbs mainly from in front and from above, the animal normally swimming on its back. The trunk limbs are phyllopodia armed with a series of backwardly projecting endites, of which the proximal is comparatively large. Food particles are drawn into the mid-ventral space by the suction produced by the forward stroke of the limbs. They are prevented from passing into the inter-limb spaces by the long setæ borne on the basal endites and are finally blown towards the mouth by the anteriorly directed feeding current.—**Charles Henry O'Donoghue and Eileen (Bulman) Abbott**: The blood vascular system of the spiny dogfish, *Squalus acanthias* Linné, and *Squalus sucklii* Gill. The objects of the paper are (1) to provide a comparative account of the blood vascular system of a generalised selachian, and (2) to revise the homologies and consequently the nomenclature of certain of the more important vessels. The fact that the branchial arches in the embryo Squalus are practically identical with those in the embryos of all the higher groups of vertebrates gives a key to the homologies of the anterior arteries. Thus, for example, the vessel termed the posterior carotid by Parker, or external carotid by other authors, is the same vessel as the stapedial of the mammalian embryo or the adult reptile.—**S. Williams**: Sporangial variation in the Osmundaceæ. There is a considerable range of variation in the sporangia of the Osmundaceæ, particularly as regards the characters of the annulus. The bearing of these variations on the systematic placing of certain fossils is discussed, and it is concluded that Kidstonia, Boweria, and possibly *Discopteris Rallii* may be assigned to some near relationship with the Osmundaceæ. The variations described also provide evidence for the view that the sporangia of the Osmundaceæ lead on to those of Plagiogyria and so on to those of the Gymnogrammoid forms.—**Claude W. Wardlaw**: Size in relation to internal morphology. (3) The vascular system of roots. The passage of water into the tracheides and wood vessels of roots is largely dependent on the close association of the living parenchyma cells with the tracheides and wood vessels. In root steles of increasing diameter, the xylem does not remain of uniformly simple structure (as in small roots) but becomes progressively disintegrated and complex. By these changes the large surface of contact with the living parenchyma cells is maintained. Thus the changes in the structure of the xylem in roots of increasing diameter are such that actual size does not act as a limiting factor to the important physiological activities of the tissues involved.—**J. Caldwell**: Localised translocation in the swede. The south-facing half of a Swede 'bulb' grown under ordinary field conditions is more largely developed than the north-facing side, and analysis shows that it contains an appreciably larger amount of total carbohydrate. Asymmetry can be induced artificially by removing the leaves from one side of the shoot during the growth of the bulb. The carbohydrate manufactured in the leaves of one side of the shoot is thus apparently stored in the corresponding region of the bulb. Confirmatory evidence of localised translocation is afforded by the behaviour of a stain such as eosin, which, when introduced at the cut end of a petiole, is distributed over the corresponding third (approximately) of the vascular cylinder in stem and bulb.

Paris.

Academy of Sciences, Feb. 27.—**Marcel Brillouin**: The kinetic theory of a gas in the neighbourhood of a wall. Position of the mathematical problem.—**Th. Anghelutza**: Generalised symmetrical and symmetrisable nuclei.—**A. Buhl**: Permutable operators and groups of transformations.—**Octav Onicescu**: The topological properties of the transformation defined by a uniform function of the complex variable z.—**Julius Wolff**: A property of a series of rational fractions.—**Ch. Dévé**: A machine with automatic epicycloidal transformations for working optical glass surfaces.—**Svyngedauw**: The deformations of the element of the pulley belt which approaches the pulley.—**E. Baticle**: The theory of equilibrium of heavy massifs submitted to pressure from below and its applicability to the stability of barrages and slopes.—**M. Mesnager**: Remarks on the preceding note.—**P. Fatou**: The sense of the displacement of the node of certain orbits.—**R. Ferrier**: Molecular geometrical specificity.—**E. Brylinski**: The velocity of the earth. Remarks on a recent communication of Piccard and Stahel.—**Girault**: The principle of relativity and the law of gravitation.—**Mario A. da Silva**: The affinity of oxygen for the electrons.—**R. Cornubert**: α-Dimethylcyclohexanones.—**L. Bert**: Houben's reaction. This is a method of preparing hydrocarbons based on the reaction $RMgX + R'X' = RR' + MgXX'$. The small yields frequently obtained by Houben's reaction appear to be due to the condensing action of the magnesium halides produced. This action somewhat resembles the action of aluminium chloride in the Friedel and Craft reaction. The yields are much improved by using as a diluent a saturated hydrocarbon such as cyclohexane or petroleum ether boiling between 70° and 90° C.—**Stanislas Landa**: The slow combustion of hydrocarbons. The slow combustion of paraffin wax by air at 280° to 300° C. The following substances have been identified among the volatile oxidation products: acetone, methyl alcohol, butyric aldehyde, methylethylketone, ethyl alcohol. Higher aldehydes were also present. These results are regarded as confirming the views of Bone on the slow combustion of hydrocarbons.—**J. Campardou** and **M. Séon**: The decomposition of the acid anhydrides. The preparation of anhydrides by direct dehydration of the acids. Some acetic anhydride is produced by the action of titanium dioxide on the vapour of acetic acid at 300° C.—**Gibault** and **P. Rougerie**: Magnetic measurements in the east of France. Results are given for 28 stations, 8 of which are new. The isomagnetic curves in this region show no marked magnetic anomaly, but in the north-west of the Department of the Meuse the slight deformation of the curves indicates a prolongation of the magnetic anomaly of the Ardennes.—**Ph. Joyet-Lavergne**: Contributions to the study of the chondriome of a fungus of the genus Saprolegnia. The filaments of the chondriome give reactions characteristic of glutathione. The chondriome possesses both oxidising and reducing properties.—**Raymond-Hamet**: The effects of the simultaneous stimulation of the vagus and of the sympathetic on the heart and on the intestine.—**Maugnon** and **E. Knithakis**: Variations of the *p*H of the blood and of the alkaline reserve in the course of watery diet in the dog.—**M. Abeloos**: The cycle of growth in *Planaria gonocephala*.—**C. Mathis**, **A. W. Sellards**, and **J. Laigret**: The sensibility of *Macacus rhesus* to the virus of yellow fever. Three specimens of *Macacus rhesus* were infected, one by inoculation with the blood of a yellow-fever patient, and the two others by bites of mosquitoes infected by the same patient. All three died from yellow fever.

ROME.

Royal National Academy of the Lincei, Dec. 4.—**F. Severi**: The correspondences between the points of a variable curve on an algebraic surface.—**G. Scorza**: The fundamental sub-groups of a group.—**U. Cisotti**: Helico-conical vortices. The designation spiral has been given to a type of plane vortices which result from the compounding of the motion due to a plane punctiform source with a circulatory motion around the same, the lines of flux being logarithmic spirals about the position of the source, to which they tend asymptotically. Prosecution of this notion leads to the development of a type of spatial vortices arising from the composition of the motion due to a spatial punctiform source with circulation about an axis containing the source; such are termed helico-conical vortices, since the lines of flux are conical helices, which give Archimedean spirals as their projections on any plane normal to the axis.—**L. Cambi** and **Ada Clerici**: The action of nitric oxide on the thiosulphates of metals of the eighth group (1). The formulæ attributed by Manchot to nickel and cobalt nitrosothiosulphates, namely, $[(S_2O_3)_2Co(NO)_2]K_3$ and $[(S_2O_3)_2Ni(NO)]K_3$, correspond as well with univalent cobalt and nickel, with NO as a neutral additive molecule, as with tervalent cobalt and bivalent nickel with NO as a residue of hyponitrous acid. The supposed univalency of the metal is based on purely formal deductions, and does not correspond with the chemical behaviour of the two compounds or with the conditions of their synthesis. The NO radicles of these thiosulphates exhibit the same behaviour as those of the nitrososulphides and are thus residues with the functions of halogens.—**P. Vinassa**: Symmetry in the electrons. Of a total of 3830 artificial organic and inorganic compounds examined, more than 3700 have even molecular numbers, so that the rule recently given for the mineral components of the earth's crust is of general application. The term *electronyl* being given to the atomic entity active by the effect of the number of electrons in excess or deficit of the nuclear charge existing in them, it may be shown that (1) the number of electronyls represented in the principal states of equilibrium is always 8 or 12, and (2) electronic numbers corresponding with groupings of five or seven electrons are always lacking.—**P. R. Pirotta**: Agrarian ecology and the International Grain Conference.—**F. Sbrana**: The approximate calculation of a harmonic function in three variables and of its successive derivatives.—**V. Hlavatý**: The reduction of orthogonal systems of linear differential equations.—**G. Vranceanu**: The trigonometrical stability of equilibrium in dynamics.—**B. Finzi**: Stationary slow motions of viscous liquid films.—**G. Krall**: Functional dependency on the outline of the Green-Somigliana tensor for elasticity equations.—**G. Andreoli**: Certain of Lie's infinite groups connected with the theory of algebra and with the absolute differential calculus.—**C. Mineo**: A formula, analogous to that of Stokes, for the determination of geoids with deviations of the vertical.—**F. Rasetti**: The intensity of the lines of the principal series of potassium. Determinations of the number of dispersion electrons for the first lines of the potassium series show that these do not obey Trumpy's law, according to which the coefficient of probability of transition from the state mP to the state S decreases in proportion to $1/m^3$, although this law holds for the higher terms of the series.—**G. Natta** and **M. Freri**: X-ray analysis and crystal structure of cadmium-silver alloys (2). The β'-phase of these alloys, obtained by re-heating the β-phase below 480°, is resolved into a mixture of crystals of the α- and γ-phases when re-heated below 200°. This transformation occurs only with solid solutions of silver in the compound AgCd, but not with those of cadmium in this compound or with alloys still richer in cadmium. The γ-phase of the system exhibits close structural analogy to the γ-phase of the brasses, and has a cubic elementary cell of side $a = 9{\cdot}99$ A., containing 52 atoms, the calculated density for the alloy with 64·1 atomic per cent. of cadmium being 9·59; the hypothetical chemical compound constituting this phase may be given the formula Ag_5Cd_8. The δ- and ϵ-phases, comprising alloys with 67 to beyond 90 per cent. of cadmium, give photograms of the same aspect, the lines corresponding with a compact, hexagonal structure having the axial ratio $c : a = 1{\cdot}58$. The η-phase has the same crystal structure as cadmium and consists of solid solutions of silver in the cadmium lattice.—**A. Quilico**: Sulphonation of phenolic ethers with aminosulphonic acid. The formation of ammonium *p*-anisolesulphonate by the action of aminosulphonic acid on anisole appears to be applicable to phenolic ethers in general.—**G. Cumin**: Certain rocks encountered in the perforations of Ripi (Latium). —**R. Fabiani**: Remains of mammifers in the Tertiary and Quaternary of Ragusa (Sicily).—**Giambattista Dal Piaz**: Outliers of the Dent Blanche in the post-Triassic formations of Grivola.—**G. Cotton Research and Industry.

IN a recent issue (Mar. 10, p. 362) we directed attention to the scientific work being carried on in the cotton fields by the Empire Cotton Growing Corporation, and the possibility of this work being checked, if not discontinued, because of the difficult position in which the Lancashire industry finds itself. The publication of the reports of the experiment stations founded by the Corporation for the year 1926–27, comes therefore at an opportune moment ; as they throw a considerable light on the character of the research instituted —probably in the long run the most important of its many activities. A sound scientific basis appears to have been laid for the success of its effort to increase the quantity and improve the quality of the cotton being produced within the British Empire. These reports are collected in a handy volume of about 250 pages, interspersed with tables, diagrams, plates and maps, and placed before the public at the low figure of half a crown.

The founding of an experiment station concerned with any particular crop is by no means so simple a matter as it might appear, and usually follows years of local study. Even when the need for it has been demonstrated and the problem to be solved has been clearly defined, a thorough survey of the country has to be made in order to determine the most suitable site, special attention being paid to such economic factors as communications, transport facilities, supplies, as well as climate and soil. It is often found advisable to take up a small area of land for a couple of years to make sure that no adverse factors have escaped notice. This preliminary survey work of the Corporation, made at a time when no staff was available for the running of the stations, deserves a passing reference. Experienced officers were deputed to travel over practically all of the cotton-growing tracts in the Colonies ; and in this work the Corporation was specially fortunate in securing the co-operation of a number of senior members of the Indian agricultural service, who were permitted to retire on proportional pensions under the Reforms Scheme. A series of valuable reports has been sent in and published, and some idea was thus formed as to where research was most likely to be profitable.

As to the staffing of the stations, a wide net was spread over the scientific and agricultural schools in Great Britain, and selected students were encouraged by scholarships to undergo post-graduate training to fit them for cotton research.

The response was on the whole good, and many of these students are already at work. The stations reported on this year are naturally in all stages of development, varying from a few acres tentatively acquired, to large ones with full equipment and buildings, and the reports are in consequence of very different interest and value. It is evident, however, that the Corporation has within a remarkably short period succeeded, in spite of great difficulties in obtaining suitably trained officers, in building up an agricultural department of an entirely novel character, namely, one devoted to the study of one crop scattered over the whole range of British Colonies in the warmer tracts. There are in the present volume reports from Queensland, the Transvaal, Natal, Swaziland, Southern Rhodesia, the Anglo-Egyptian Sudan, Uganda, Nyasaland, Nigeria, and Fiji, prepared by plant breeders, entomologists, and agriculturists in charge of separate areas.

It must be remembered that the research work recorded in the pages of the reports is only a portion of that being conducted by the officers of the Corporation. The Cotton Research Station in Trinidad is not included; and it is somewhat difficult to draw the line between the Corporation's work and that of the existing agricultural departments of the various Colonies, because there seems to have been a gradual drafting of men sent out by the former into the expanding Colonial service, whenever it has been found possible to allocate funds for the purpose. The unity of aims and the perfectly amicable relations existing between the officers under these two controlling bodies is a marked characteristic of the work of the Corporation.

Before proceeding, however, to more detailed reference to the character of the scientific work embodied in these reports, it is natural to inquire why the local agricultural departments cannot deal with the work undertaken by the Corporation; and also why this particular crop—cotton—needs financial assistance from Great Britain, as against such staples as rubber, tea, and sugar, for which research is provided for locally. The answer to the first question is fairly simple. The agricultural department in any colony has charge of the whole of the crops grown within its limits; and it can rarely afford to depute an officer entirely to the study of one crop, however important.

The second question is not capable of quite so simple an answer, because it depends on the distribution of capital. The capital connected with the cotton industry is located in Lancashire, while that in tea, sugar, and rubber lies chiefly in the places where these crops are grown. The cause for this is to be found in the character of the raw material yielded by the plant in either case. The cotton plant produces, naturally, in the fields, a raw material in its finished state; and all that is required is for this to be collected, kept dry and clean, and sold to the local buyer for pressing and forwarding to the mills at home. But in tea and sugar, and at present in rubber, the produce of the plant is in such a condition that it has to undergo complicated treatment before it can be sent across the ocean. Taking sugar as an example, the canes are full of sweet juice which has to be expressed, and which is then liable to rapid deterioration in the air; and the more stable sugar has to be extracted from it on the spot as expeditiously as possible. Furthermore, the canes grown on an acre of land will vary in weight from, say, 20 to 50 tons or more, and the transport of this mass of material to the crushing mill is an important item of expenditure. For both of these reasons the sugar factory must be placed as near to the cane fields as possible; and the capital for the erection of an efficient, up-to-date sugar factory will run to some £200,000. A similar location of factory on the plantation is also necessary for tea and rubber; and in all three cases a large tract of land must be acquired and put permanently under one crop—which, in effect, adds considerably to the capital to be sunk on the spot. Moreover, whether the selling price be high or low, cultivation must proceed and the factory be kept going: in sugar, at any rate, closing down the factory in lean years would spell ruin.

The growing of cotton is under entirely different conditions. There is no local capital involved, and anyone who owns a bit of land can either grow it or not at will; when prices are high the area increases, and when low other crops are grown instead. Rotation of crops, practically impossible in the other staples mentioned, is a prime necessity, and is everywhere practised in native cultivation; therefore a change of crop is easily effected. To attempt to collect a levy on the growers for the prosecution of research would immediately curtail the area sown, and thus defeat the object in view. It is obvious then that, with cotton, the capital required to finance research must come from the mills; and the Cotton Corporation, as representing them, takes the part of the fairy godmother to the cotton growers. It acts on the principle that improving the quality is the surest way to increase the quantity, in that it enhances the price received by the cultivator; and thus the two aims of the Corporation are inseparably connected. The most encouraging features in the project are that the class of cotton raised in British Colonies is, as a rule, distinctly better than that grown in the United States, which it is designed to replace; and also that land and labour cost less, and therefore it can be more cheaply produced.

One glance through the reports will convince anyone that each tract has its own set of problems, and in most cases may have its own limiting factors; and the idea of one central experiment station devoted to cotton growing can at once be abandoned. In the Union of South Africa the annual rainfall is the basal factor, and has been found to be distinctly unreliable; and, in addition, a minute insect attacks the leaves to such an extent that it is essential to breed types resistant to this pest. In Nigeria the limiting factor seems rather to be competition with other crops, coupled with transport difficulties, and a cotton fetching a high price is needed. Nyasaland is chiefly concerned at present with working out the most suitable rotations for three sets of conditions: European plantations, and native cultivation for high and low areas. Fiji is devoted to the finer counts, and can grow Sea Island cotton, but, owing to the practical disappearance of the market for this during recent years, is concentrating on obtaining a long-stapled type which is more marketable. Queensland, however well she may grow cotton, will sooner or later have to face competition between that raised by white labour and native grown from elsewhere. The Anglo-Egyptian Sudan, with its varying conditions of moisture—obtained solely by irrigation, by rainfall, and by the two together—practically covers the whole field of cotton breeding and cultivation. Speaking generally, these tracts appear to be able to grow perfectly good cotton, but all require the services of (1) plant-breeders to evolve the most suitable type of cotton to be grown, (2) entomologists to preserve it from the local insect pests, and (3) agriculturists to grow healthy crops at the least possible cost.

Probably the most promising direction for a permanent increase in cotton growing in the British Empire is at the moment in India, but that country has its own problems and its own well-developed scheme of cotton research. There are vast possibilities in the Sudan, and great hopes are entertained in the Union of South Africa.

It will be sufficient here briefly to refer to the work being carried out in these two places. The outstanding factor in South African research is the Jassid infestation, which has practically wiped out the standard varieties hitherto relied upon. It has been observed that hairiness in the leaves is a distinct hindrance to the development of this insect; and the plant-breeder at Barberton has succeeded in evolving hairy forms strongly resistant to the Jassid, and at the same time with the good qualities of those forms it is necessary to replace. This result is being hailed with satisfaction by the planters everywhere, and the strains obtained will apparently also be required in Southern Rhodesia. This piece of research is particularly creditable, in that it has been conducted under most disheartening conditions; a record drought has visited South Africa during the last three years, again and again spoiling the experimental plots.

The report from the Sudan covers more than forty pages; but considering the large tract of country dealt with and its greatly varying conditions, this is not at all excessive. Special attention is now being paid to the southern, more tropical section, where a good deal of native cultivation has been inspected during the year. Although there is plenty of work still to be done in the northern, irrigated areas, it is perhaps to this southern rain-fed tract that we may look for the greatest permanent increase in cotton growing. A good deal of exploratory work is thus included in the report, and this portion is extremely interesting. Observations are recorded on the gradually changing vegetative covering of the country, with the increasing rainfall on going south; and studies are mentioned of root range and the character of the different layers of soil in various place—always a matter of interest in the Sudan—as indicating likely areas for expansion. Variety plots have been laid down and a certain amount of selection has been begun among the native-grown crops.

It is obvious that a great deal of important scientific work is being done on the Corporation's experiment stations, all tending towards the ideal of making the Lancashire mills less dependent on the vagaries of the United States cotton supply; and it would be little short of a disaster if the work were checked at the present stage.

When a new disease broke out in the Java canefields and swept through the island from end to end, the planters, although smarting from a loss of £200,000 in one year, came together and agreed to tax themselves in support of a scientific department to fight the disease. The amount of the levy was at first small, but it paid so well that it has been gradually increased, until the annual amount spent on scientific work is at present £100,000. Again, when the trade slump in 1921 threatened the Hawaiian sugar industry, the attitude of the heavily hit planters was expressed by the director of the experiment station in the following motto: "More investigation, more experimentation, more research, leading to higher yields per acre and lower costs per ton of sugar"; and there was no suggestion of the planters cavilling at this increase in their levy.

One result of the action in these two instances appears to-day in the fact that Java and Hawaii are producing more than five tons of sugar per acre, against round about two tons in all the other chief cane-growing countries[1]—a matter of some significance now that the sugar industry is in low water. The tea and rubber planters have within the last few years started their own research stations; at any rate one sugar concern, the Colonial Sugar Refining Company, runs its own agricultural, entomological, and mycological research; and a perception of the losses incurred by disease has in one case caused this company to multiply its mycological staff, so that every field on every estate can be thoroughly surveyed, and appropriate cultivation and scientific remedies applied. It is to be hoped that such will be the feeling inspiring the action of the Lancashire cotton trade, in the present deplorable condition of the larger section of this industry.

Botanical Records in the Rocks.

Handbuch der Paläobotanik. Von Prof. Dr. Max Hirmer. Mit Beiträgen von Dr. Julius Pia und Dr. Wilhelm Troll. Band 1: *Thallophyta, Bryophyta, Pteridophyta*. Pp. xvi + 708. (München und Berlin: R. Oldenbourg, 1927.) 48 gold marks.

IN a 'handbook' of palæobotany, botanists, geologists, and others interested in the story of plant-life in the past expect to find a summary of the labours of students who have made it their business to collect and interpret the botanical records of the rocks. Prof. Hirmer's volume in the main satisfies this requirement. Among the many questions which experts are expected to answer we may include the following: What light is thrown upon the evolution of plants by the samples of vegetation preserved in sedimentary strata? Does a comparison of the successive floras which have flourished on the earth's surface afford evidence of a continuous progressive development from simple to more complex types? Or is there reason to believe that a comparison of extinct and recent plants demonstrates a marked tendency towards recurrent cycles—a rapid rise to power and the successful colonisation of wide spaces on the part of certain groups, followed by their decline and by the apparently sudden appearance of new dynasties destined for a time to play the leading rôle in the world's vegetation?

In the second volume the author will no doubt deal with some or all of these general questions. The volume before us is mainly descriptive and carries us to the end of the Pteridophyta. Dr. Julius Pia contributes an introductory section on the preservation of plants as fossils, and to him have also been entrusted the Algæ and Fungi. No text-book of palæobotany is considered to be complete without a chapter on the various methods of fossilisation: there is, however, one aspect of the subject which is generally overlooked or inadequately treated. The present is in many respects the key to the past: geologists are accustomed to speak of the imperfection of the record, and it needs but little imagination to realise that the emphasis placed by Darwin on this imperfection was not exaggerated. On the other hand, we should be in a better position to form a just estimate of the proportion borne by fossils to the mass of contemporary vegetation if we had a fuller knowledge of what is now happening in different areas inhabited by trees or by herbaceous plants. We should like to know more about the conditions under which rivers are now accumulating in the sediments of deltas representative samples of the vegetation on their banks and on the higher ground watered by the parent streams; the relation of woody to herbaceous plants; the capacities of different kinds of vegetable debris to resist wear and tear; and so on. One suspects that many of the older floras are represented in the rocks almost exclusively by plants that were confined to certain habitats. By a closer study of the processes of rock-building at the present day, it might be possible to estimate with greater precision the chances of preservation of material derived from different geographical regions. Hints on the preparation of unpromising specimens for microscopical examination would have been a useful addition to the chapter on fossilisation.

The account of calcareous Algæ is on the whole very satisfactory; it directs attention to the wealth of form of such Algæ as the Dasycladaceæ in Mesozoic and Tertiary seas as compared with the relatively small number in the seas of to-day. The treatment of fossil Bacteria, of the problematical genera Pila and Reinschia, and of some of the other supposed Thallophyta, might with advantage have been more critical. Dr. Pia unfortunately reverts to the old name Prototaxites for the Silurian and Devonian plant which is usually known as Nematophyton, and he assigns it to the Brown Algæ. The systematic position of this genus is still very uncertain, but it is almost certainly not in the Phæophyceæ. At the end of each section is appended a bibliography, which is usually adequate. Dr. Troll gives a useful survey of the Bryophyta and directs attention to the important discovery by Mr. J. Walton of specimens of very modern-looking Liverworts in the English Coal Measures.

---

[1] Maxwell, "Economic Aspects of Cane-Sugar Production," p. 57.

The greater part of the volume is written by Prof. Hirmer, who compresses much into his well-illustrated descriptions of the Palæozoic representatives of the several groups of Pteridophyta. Most of the figures are taken from previously published books and papers: diagrammatic drawings illustrating morphological features are a welcome addition, and restorations of Lepidodendra, Sigillariæ, and Calamites are in many respects an advance upon previous attempts. Students will be grateful to the author for having collected much information from widely scattered sources and for making it available to the botanical reader. In his summaries of the morphological characters at the end of the descriptive accounts, he makes many suggestive comparisons of extinct and living types, but he tends to over-emphasise points of detail, and does not sufficiently consider readers who desire to know in what respects such plants as Lepidodendron, Calamites, and other Palæozoic forest trees differed from their modern descendants.

In the account of Psilophytales, Rhynia and Psilophyton are placed in different families, a separation which it would be difficult to justify. The lack of secondary phloem in stems of Lepidodendron well provided with secondary wood is an interesting fact worthy of greater prominence. No evidence is furnished in support of the statement that Asterocalamites was widely distributed in Upper Devonian floras. The account of Mesozoic ferns compares unfavourably with that of the Palæozoic genera; it fails to bring out the contrasts in geographical range between extinct and recent species, and it does not sufficiently illustrate the relative antiquity of the several families. There is no reference to an important paper by Prof. Halle on the schizæaceous fern Ruffordia, and Dr. Bommer's description of Weichselia, a fern assigned on insufficient data to the Cyatheaceæ, is overlooked.

Such criticisms as have been made are not intended to be an expression of disapproval of the volume as a whole: on the contrary, the reviewer heartily welcomes the publication of a work which in some respects differs from all earlier books on palæobotany. The author undertook a very laborious and difficult piece of work; the first volume is by no means free from errors and its descriptive summaries are very unequal in value. We look forward with interest to the appearance of the second volume. A. C. S.

Lucretius.

T. Lucreti Cari de Rerum Natura libri sex. With Notes and a Translation by H. A. J. Munro. Fourth edition, finally revised. Vol. 2: Explanatory Notes. With an Introductory Essay on the Scientific Significance of Lucretius, by Dr. E. N. da C. Andrade. Pp. xxii + 424. (London: G. Bell and Sons, Ltd.; Cambridge: Deighton Bell and Co., 1928.) 12*s.* 6*d.* net.

MUNRO was the chief scholar in Cambridge fifty years ago, and his study of Lucretius gave him a prestige such as pure scholarship confers no longer upon any man. He was a perfect editor in his own scholarly way; yet he brought little sympathy and less knowledge to bear on the scientific doctrines taught in the great scientific poem which he edited. He admits that Lucretius has produced "a very complete and systematical account of the natures and properties which belong to the two great constituents of the universe, matter and void"; but Munro says bluntly that "We of course care not for the scientific value or truth of the poem, but for its poetical grandeur and efficacy upon our imaginations."

Indeed it is full of fine things which charm our ears and stir our imagination. Phrases like 'mors immortalis' or 'flammantia moenia mundi' cling to the memory; the whole parable of the Talents is wrapped up close in 'vitaque mancipio nulli, datur omnibus usu'; and after two thousand years 'tantum religio potuit suadere malorum' has not lost its sting. But after all, scientific doctrine and not literary beauty is the main thing in this, the one great scientific poem of the world: so scientific men have prized this great epic for 'its scientific value or truth' ever since it was written. Celsus and his brother physicians (the scientific men of Rome) were all Epicureans; and doubtless knew the poem by heart; Giordano Bruno and Gassendi preached its doctrines and impressed them on seventeenth century philosophy just when physical science was awaking to its first golden age; Boyle quotes the poem repeatedly; and later on Tyndall, Clifford, Kelvin and Clerk Maxwell himself, in their several ways and degrees, admired and praised it. Newton found in it (among other important things) a clear statement of the Galilean principle of the falling body: "Et quamvis res leviores, quæ æris vel aquæ resistentiam difficilius vincunt, in his fluidis descendant tardius, tamen in spatio vacuo ubi nulla est resistentia atomos omnes tam graviores quam minus graves propter gravitatem sibi proportionalem æquali celeritate descendere, *sic docet Lucretius*."

Lucretius attributes the phenomena of the world to necessity, or as we should say, to physical law: 'nam certe neque consilio,' for verily not by design, was the world made. He holds just as Bacon did, that teleological explanation should be left severely alone by the natural philosopher; he understands as well as did Lagrange, that (to borrow a phrase from Larmor) the great desideratum of a science is its reduction to the smallest number of dominating principles; and the greatest of all these dominating principles he found in the atomic theory. Within our own lifetimes the atom was but an hypothesis, first a useful, then an indispensable hypothesis—one of the most potent of scientific *Denkmittel*, or modes of economising thought. Then Maxwell, Clifford and Kelvin began to show that atoms *must* exist, and nowadays we know at last that they *do*. They are no longer hypothetical, but as real as any other objective things; and we wonder more than ever before at the marvellous insight and prescience of the ancient founders of the atomic theory.

Less than a twelvemonth ago I paid my last visit to Arrhenius. As we walked past the Museum hard by his house, and looked up at the great names inscribed upon its walls, Arrhenius said, "Surely Democritus was the greatest of them all." It was the mantle of Democritus which Epicurus wore, and it was at Epicurus's feet that Lucretius sat to learn the story of the atoms; but who it was that had told it to Democritus we do not know. Democritus was a rich man's son in a provincial town, about the time when Xerxes drew his broken fleet and army home from Salamis; he has left nothing of his very own, save a few hearsay fragments and broken sentences out of his many books. Yet at this day a great physicist looks on him with something like awe, and speaks of him with reverent admiration; for he was the father, so far as all our pedigrees can go, of the most fundamental postulate of all physical science.

The shadows which surround the person of Democritus are but part and parcel of the mystery which hides the origin of the Greeks and the sources of their wisdom. Pythagoras, Thales, Heraclitus, and others besides Democritus are shadowy and all but legendary figures; we trace our science and learning back to them almost as the Japanese trace their empire to the sun and moon. But even Greek wisdom did not come straight from heaven; there were brave men before Agamemnon and wise men before Democritus. The world had rung with the clash of armies and the fall of ruined empires before the day of Greece began; time and again an old order passed away, giving place to new; but doubtless when almost everything was lost, a few seeds of ancient learning, Hittite, Chaldean, Cretan, Egyptian and what not, fell upon good Greek soil and multiplied an hundredfold. Our ignorance of what did happen, and how and when, is the deepest puzzle and the greatest romance of history.

While Democritus's own words are all but vanished, and very few of Epicurus's remain, Lucretius's poem gives us the completest, plainest account we have of any ancient system of philosophy; we read it without effort, and reading it we feel at home. Though we translate Plato and Aristotle into our own tongue, the language they speak is not yet our own; nor do they think and reason in our modern, western way. But any of us may read Lucretius, and under all his splendid diction find nothing hard to follow, nothing anomalous or strange. The present re-issue of Munro's "Lucretius" is vastly the better of a short preface (of some twenty pages) on the scientific significance of Lucretius, by Prof. E. N. da C. Andrade; who not only gives us a singularly clear epitome of the Epicurean philosophy, but also manages to illustrate it by modern instances in a wonderfully happy way. For example, Prof. Andrade not only reminds us of Le Sage's corpuscular, or atomic, theory of gravitation, but also tells us that Le Sage entitled his treatise "Lucrèce Neutonien"; that in short, he got it from Lucretius, and acknowledged the debt. Prof. Andrade shows us how Sir Isaac Newton and Sir William Bragg went straight to Lucretius for the phrase "the Nature of things,"—as before them no less a person than Paracelsus had also done. Again, he shows how Lucretius supposed the atoms of a solid (unlike the smooth round atoms of a liquid) to be hooked and so to cling together; and how these hooked atoms were used in the seventeenth century, even by John Bernoulli himself, and how they have served their turn again with modern chemists to explain chemical combination and valency. Only yesterday (I mean fifty years ago) Crum Brown used to describe to us beginners the carbon atom, with its four little hooks or 'hands,'—as Kekulé's flash of insight had conceived it a few years before, in that Annus Mirabilis when the "Origin of Species" appeared. As for the smooth round atoms to which Lucretius attributed the fluidity of a fluid, they come pretty near to Dr. Harold Jeffreys' brand-new concept of the structure of a liquid, as formed of 'units' (each an aggregate of molecules), 'perhaps roughly spherical,' and mobile on one another.

Each generation may study Lucretius in the light of its own knowledge. Gassendi compared his teaching with that of Copernicus and Kepler and Gilbert; we think of him in the light of J. J. Thomson's work, and Rutherford's and Bragg's. Prof. Andrade even shows how Dr. G. C. Simpson's newest theory of thunderstorms, with the raindrops borne up on rising air-currents, has its counterpart in the 'seeds of fire' which, according to Lucretius, are carried up into the 'hollow clouds.' I am inclined to think that the sixth book, in which this and other meteorological passages occur, is mostly derived from another source; and, interesting as it is, is less profound than the more strictly Epicurean portions of the poem.

The whole epic is but a short one, of some seven or eight thousand lines; but there is scarcely a passage in it which has not some close and peculiar interest for ourselves. The hereditary germplasm of Weismann, and Darwin's 'pangenesis,' are no other than the Lucretian doctrine of 'primordia,' which, variously combined, lurk hid within the parent's body and are handed on from father to son—'quae patribus patres tradunt a stirpe profecta.' The conservation of matter is proclaimed more than once; and with the utmost clearness: 'res . . . non posse creari | de nilo neque item genitas ad nil revocari'; or again, 'nam neque adaugescit quicquam neque deperit inde.' The conservation of energy is almost as clearly laid down. The very atom itself is declared not to be in ultimate analysis; but itself to consist of certain *minima*, which never did and never will subsist of themselves, for of their very nature they are primary and minimal constituents of the other—'alterius quoniam est ipsum pars primaque et ima.'

On one strange point of the Lucretian doctrine (the kernel of the whole thing, according to some) Prof. Andrade says very little; though what he does say is very much to the point. This is that *exiguum clinamen*, by which the atoms swerve ever so little, and only now and then, from their straight determined path: and so are brought into collision, which collisions are the starting-point of a new order of things. Thus a certain freedom of action is possessed even by the atom, and is the first faint adumbration of our own soul's free-will —'unde haec est nobis innata potestas.' Here Lucretius tries, as did Epicurus, to get behind the more unqualified and more relentless materialism of Democritus. It reminds us of that 'something more' which many a physiologist is constrained to postulate when physical science fails him to explain the humblest of his vital phenomena. It reminds us in a more apt and more important way (without our pressing the analogy too far) of Newton's famous scholium: "a cæca necessitate, quæ eadem est semper et ubique, nulla oritur rerum variatio." D'ARCY W. THOMPSON.

Early Man and Civilisation.

(1) *Ancient Civilisations: from the Earliest Times to the Birth of Christ.* By Donald A. Mackenzie. Pp. xix + 283 + 12 plates. 12*s.* 6*d.* net. (2) *Footprints of Early Man.* By Donald A. Mackenzie. Pp. xviii + 190 + 16 plates. 5*s.* net. (London and Glasgow: Blackie and Son, Ltd., 1927.)

WITHIN recent years the evidence relating to the extinct members of the human family and the cultural achievements of the pioneers among our own species has increased at such a rapid rate that the intelligent public, and not a few of the professional archæologists themselves, are apt to be bewildered in the face of all this new information. Few of those actually engaged in the work of recovering this new evidence have the time or the wider knowledge successfully to undertake the task of interpretation and exposition. A legion of writers has rushed in to supply this widely felt need; but, unfortunately, most of them have not exercised their own judgment, but have simply followed one or other of the professional authorities. Hence, Mr. Donald Mackenzie, a writer of great literary ability, who has read widely and critically, and with independent judgment has interpreted what he has learned in the light of his knowledge of the folk-lore of the Scottish Highlands, has come to occupy the unique position of an independent and lucid expositor of the progress in this difficult department of anthropology.

In the larger of his two new books he discusses in a fresh and interesting way the origin of civilisation and the history of its development in Egypt, Crete, Sumer, and Mesopotamia, with brief but illuminating sketches of the origins in Persia, India, and China, and many apt illustrations, culled from other places, of the factors involved in the process of invention of arts and customs.

The smaller book is concerned mainly with the remains of extinct types of man—a subject with which Mr. Mackenzie is not so familiar—but it also presents a clear sketch of the field covered by the larger work.

Both books include accounts of the most recent discoveries, and reveal a nicely balanced perspective in the view they present of the whole field of inquiry. What lends a particular charm to Mr. Mackenzie's work is the series of scraps of apt corroborative evidence which he collects from unexpected places and weaves into his lucid and entertaining narrative. For example, he has been able to discover several important references, ancient and modern, to that too much neglected region, the Wadi Alaqi in Nubia, which in all probability was the first place in the world's history where metals were worked. The ancient mines of gold and copper ore are said in one of Mr. Mackenzie's quotations to cover an area of one hundred square miles.

These books are so excellent and useful that they are sure to run into new editions. Hence it seems to be worth while to direct attention to some of the statements that need modification. Rhodesian man did not have "a more highly developed brain" than Neanderthal man ("Footprints," p. 51); nor is it accurate to say that Piltdown man had a head such as is described on p. 14, or is "nearer to the modern man species than was the Neanderthal" (p. 168); it was Dr. Lawrence Balls, and not Mr. Lucas (p. 177), who identified the botanical material from mummies; the late Prof. Montelius was a Swede, and not a Frenchman (p. xviii), and Mr. Charles R. Knight did not visit the Rancho-la-Brea pits or see the material collected there (p. 24). In the larger book the statement that "the maximum date for the dawn of the Palæolithic Age is 125,000 B.C." calls for correction; and in both works a source of confusion would be avoided if the word "neolithic" were omitted altogether.

In spite of these lapses, the books are perhaps the best introductions to their respective subjects at present available.

Our Bookshelf.

A Handbook of the Birds of Eastern China (Chihli, Shantung, Kiangsu, Anhwei, Kiangsi, Chekiang, Fohkien and Kwangtung Provinces). By J. D. D. La Touche. Part 4 (containing Families Ploceidæ, Fringillidæ, Bombycillidæ, and Hirundinidæ). Pp. 293-398 + plates 10-13. (London: Taylor and Francis, 1927.) 7*s*. 6*d*. net.

The present part of Mr. La Touche's "Birds of Eastern China" contains the Families Ploceidæ, Fringillidæ, Bombycillidæ, and Hirundinidæ, the sequence adopted by the author being the same as that in the new edition of "The Avifauna of India." The present part nearly concludes the true passerine birds, and we understand that Part V. will include the remaining Passeres and, we hope, the Pico-Passeres, containing the Woodpeckers, Barbets, and other forms very richly represented in China.

Of the true finches, the author includes twenty-six species and sub-species, whilst of buntings there are no fewer than thirty. We must note that in the centre of the genus Emberiza, the author has evidently, by mistake, interpolated the two genera, Passerina and Calcarius. It is true that many systematists lump all three genera under Emberiza; even those who do, however, usually place these two genera either at the end or at the beginning of the group. In dealing with the Fringillidæ, we are struck by the remarkable knowledge displayed by the author of the habits and nidification of so many of its members, a fact that adds very greatly to the interest of the work. We notice that Mr. La Touche still includes the sparrows with the finches, and we are inclined to agree with him that, so far as our present knowledge goes, it is impossible to divide them, although, as Sushkin has pointed out, the sparrows have many characters which seem to ally them to the Ploceidæ or Weaver-birds.

The present part is fully up to the standard set by the author in the first three parts, and we anticipate with pleasure an early issue of the fifth part. The photographs at the end of the book are not only beautiful in themselves but also undoubtedly are a great help in assisting one to understand the country on which the book is written. The map included is merely the previous map issued, in which certain corrections have been made.

Synthetische und isolierte Riechstoffe und ihre Herstellung. Von Dr. Rudolf Knoll. (Monographien über chemisch-technische Fabrikationsmethoden, herausgegeben von L. Max Wohlgemuth, Band 10.) Zweite, vollständig neu bearbeitete und erweiterte Auflage, von Alfred Wagner. Pp. viii + 257. (Halle a. Saale: Wilhelm Knapp, 1928.) 14·50 gold marks.

In the new edition of this book the author has maintained the general plan of the original, but the process of revision has necessarily entailed a considerable expansion of certain sections. The descriptions of apparatus and plant used in isolating and synthesising perfumes and their components form a particularly useful feature of the work; the general treatment is here supplemented by particular references to the manufacture of important specific substances, such as phenylethyl alcohol, cinnamic acid, salicylaldehyde, piperonal, and synthetic musk. The descriptions of quantitative determinations and of individual substances, although brief, are on the whole adequate for the purpose in view. This section of the book, however, cannot be exonerated from sins both of omission and commission: for example, the account of synthetic menthol is restricted to a mention of the reduction of menthone and pulegone with an excess of nascent hydrogen; and it is incorrectly stated (p. 82) that *d*-menthone, like *l*-menthone, yields a mixture of *l*-menthol and *d-iso*menthol when treated in this way. It need scarcely be pointed out, moreover, that *l*-menthone is not converted to *d*-menthone when treated with sulphuric acid, "nach der Inversionsmethode von Beckmann" (p. 164).

The references to natural sources could be augmented with advantage, and some of the existing references need correction: thus, it is surprising to find in this revised work a repetition of the statement, long since proved to be without foundation, that *l*-menthone occurs in the essential oils of *Eucalyptus hæmastoma*, *E. dives*, and *E. radiata*. A useful feature of the book is a list of thirty-two continental perfumery firms, together with a summary of the products in which they specialise.

J. R.

(1) *The Industrial Arts: their History, Development, and Practice as Educational Factors.* By Frederick J. Glass. Pp. xxiii + 311. (London: University of London Press, Ltd., 1927.) 12*s*. net.

(2) *Stencil Craft.* By Frederick J. Glass. (The Artistic Practical Handicraft Series.) Pp. vii + 64. (London: University of London Press, Ltd., 1927.) 1*s*. 6*d*.

IT is easy to recognise in any book by Mr. Glass the work of one whose knowledge is only equalled by his power of expressing his thoughts, not merely with the force of the artist, but also with the literary finish of a master. It is true that he makes a lapse respecting a so-called 'quotation' from Kipling, and in "The Industrial Arts" he wrongfully describes as "plate tracery" the lancet windows of Fig. 16. In this book, as in others, he develops the lines upon which teachers should advance in the instruction of their pupils in craftsmanship. It is barely exaggerative to remark that he surveys the crafts "from China to Peru"; what does he *not* touch upon, indeed? Incidentally, it scarcely seems accurate to describe Boccaccio as of "the same age" as Savonarola and Macchiavelli; he died long before either of these two saw the light. A few notes upon stencilling merely supplement the special handbook (2) on this subject, which Mr. Glass has just produced in a series of manuals recently noticed in NATURE. His books perhaps err on the side of recommending too comprehensive a study in the schools; his enthusiasm carries him away—but then it is such a generous enthusiasm.

P. L. M.

Physics in Medical Radiology. By Prof. Sidney Russ, Dr. L. H. Clark, and B. D. H. Watters. Pp. xii + 234. (London: Chapman and Hall, Ltd., 1928.) 12*s*. 6*d*. net.

THIS book has been written primarily for the use of candidates preparing for the examinations of various universities for a diploma in medical radiology and electrology. The information it provides is given in an exact and lucid manner, and the book is not only well adapted to meet the needs of the students it caters for, but should also appeal to other practising medical radiologists.

Some minor points call for comment. The data on p. 45 refer to the absorption of ultra-violet light by *dead* tissue. Some recent evidence has been obtained showing that the penetration through *living* tissue may be much greater. The half-life period of radium is given as 1680 years on p. 88, and 1760 years on p. 93, and certain of the constants quoted for other radioactive substances are not quite up-to-date.

We expected to find some reference in Chap. viii. to Duane's method of determining the 'effective' wave-length of a heterogeneous beam of X-rays, and also in a later chapter to the theory and use of an auto-transformer.

Two valuable appendices give the revised recommendations of the British X-ray and Radium Protection Committee, and a description of a hospital radium service. A misprint in the latter on p. 218 gives 'my' instead of 'our.'

The book can be recommended with confidence.

Apollonius: or The Present and Future of Psychical Research. By E. N. Bennett. (To-day and To-morrow Series.) Pp. 95. (London: Kegan Paul and Co., Ltd.; New York: E. P. Dutton and Co., n.d.) 2*s*. 6*d*. net.

THIS review of the achievements and hopes of psychical research appears to be written without bias and with an undiminished confidence in the future. It wisely concentrates on the psychological aspects of this kind of research, and does not claim any authenticity for the physical phenomena which have so largely figured in its records. "In view," we read, "of the more immediate results of real value which may be secured from a study of the subjective phenomena of psychical research it is obvious that, unless a physical medium is willing sooner or later to submit himself frankly and honestly to every reasonable test proposed by the best scientific minds, it is comparatively useless for a researcher to spend his limited time in inconclusive sittings for the alleged marvels of telekinesis or materialisation."

Whatever may be the eventual value of the investigations of thought transference and automatic writing, there is no doubt that psychical research has rendered a service in throwing light upon many dark corners of the past.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Specificity of Ergosterol as Parent Substance of Vitamin D.

An interesting relationship between chemical structure and potential biological activity has become apparent during the course of the work which started from the observation that ordinary cholesterol is rendered antirachitic by ultra-violet irradiation. As is now well known, it is not cholesterol itself, but an impurity contained in it in minute amounts which enables it to be activated, and this impurity is most likely identical with ergosterol, the characteristic sterol of fungi (ergot, yeast, etc.). A consideration of the molecular structure of sterols in this connexion leads to the suggestion that not only the presence of the unsaturated carbon linkings, but also their number, is a deciding factor in the photo-chemical production of vitamin D from ergosterol. Thus the saturated sterols, coprosterol, di-hydrocholesterol and di-hydrositosterol remain inactive after irradiation. Further, neither cholesterol nor sitosterol with one double bond, nor stigmasterol, cholesterylene, oxycholesterylene, and di-hydroergosterol, with two such linkings, can be activated. Ergosterol with three double bonds, however, possesses this property to such a high degree that its calcifying action can be demonstrated even in daily doses of 1/100,000 mgm. in rats, whilst daily doses of 2-4 mgm. cure rickets in children.

It became, therefore, of considerable interest to investigate whether the photo-chemical change connected with vitamin formation was specific for ergosterol, depending on the position of the three double bonds in the molecule, or whether other substances with three or more double bonds would also yield the vitamin on radiation. We had already previously established that squalene, the open-chain di-hydro-triterpene with six double linkings occurring in the livers of elasmobranchs, cannot be activated, and the same holds for the oxygenated olefinic terpenes, nerolidol and pseudo-ionone. The tentative conclusion seems justified that unsaturated open-chain compounds cannot be activated.

A relatively mild chemical treatment, that is, removal of hydrochloric acid from its hydrochloride, leads from ergosterol to iso-ergosterol. Although this isomer contains three double bonds, differing in their position only from those contained in ergosterol, it cannot be activated. This also holds for a second isomer, neo-ergosterol, obtainable from ergo-pinacol by distillation. From all this evidence, which results from the work of several observers, including especially Windaus and his collaborators and ourselves, it would appear that not only a typical ring-structure, but also a specific position in the molecule of the three unsaturated bonds, is essential for photo-chemical conversion into vitamin D.

This generalisation, however, would seem to be invalidated by the statement of Windaus and Holtz (*Nachr. d. Ges. Wissensch.*, Gottingen, 1927) that digitaligenin, the aglycone of the digitalis glucoside, digitalinum verum, can be rendered antirachitic by irradiation. Since digitaligenin is a hydroxy-lactone containing three double bonds and is structurally related to cholic acid, another sterol derivative, its activation would not seem improbable. The statement has already been accepted in the literature and has led to the deduction of the existence of more than one vitamin D in Nature.

A detailed consideration of Windaus and Holtz's experimental technique, however, leaves their conclusions open to doubt, since a solution of digitaligenin in olive oil was used for irradiation. The obvious criticism arises that the choice of olive oil as a solvent for this type of experiment is an unfortunate one. It is well known that olive oil itself becomes antirachitic when irradiated, a property common to vegetable oils in general. We re-examined this question by irradiating for the biological tests an alcoholic solution of digitaligenin under the same conditions as an alcoholic ergosterol solution. The irradiated substances, freed from alcohol and dissolved in inactive olive oil, were tested by our usual technique on rats of the same litter. The irradiated digitaligenin was given in doses of 1/10,000, 1/5000, 1/250, and 1/100 mgm. and was found entirely inactive, whilst the control rats, receiving 1/10,000 mgm. irradiated ergosterol, were free from rickets. In view of the correlation existing between the ultra-violet absorption spectrum and the potential activity of ergosterol, it was of interest to examine digitaligenin in this respect. We found, as was to be expected, that this unsaturated substance showed a strong absorption in the ultra-violet, differing entirely in character and position, however, from that of ergosterol. Instead of three absorption bands, of which the one at $280\mu\mu$ characterises ergosterol, digitaligenin shows only one band with a maximum at $340\mu\mu$, extending from $270\mu\mu$ to $390\mu\mu$. In addition, there is general absorption, and possibly secondary bands, in the region below $250\mu\mu$. Moreover, the broad absorption band of digitaligenin remains practically unchanged after two hours irradiation, whereas the ergosterol bands rapidly disappear under these conditions.

The fact that digitaligenin cannot be activated strengthens the assumption that only a molecular structure, such as that possessed by ergosterol, enables a sterol to be photo-chemically converted into vitamin D, and confirms the evidence already available for the view that ergosterol is the specific parent substance of vitamin D.

Lead Tetraethyl in Internal Combustion Engines.

While looking through the article by Dr. E. Mardles in NATURE of Mar. 17, my attention was arrested by Table V. This table, the origin of which is not stated, appeared in a Report of the U.S. Bureau of Mines, dated December 1924 (Serial No. 2661).

Dr. Mardles gives this table as a typical analysis of the deposits, but it should be emphasised, as I have endeavoured to do in another journal, that there is no such thing as a typical analysis of these deposits, because the deposits vary in quantity and kind according to the conditions of engine operation. With one engine, for example, it is possible to obtain 9 per cent. or 17 per cent. or 36 per cent. of the lead supplied in the petrol, in the deposits on the cylinder heads and pistons. The percentage can be fairly accurately controlled by varying the conditions of operation.

Just above Table IV. in Dr. Mardles' article, the statement is made that "The results of prolonged engine trials with fuel containing not more than 6 c.c./gal. confirm the claims made that ethyl petrol will not injure spark plugs, valves, or stems." As against this statement may be quoted the following from a very noteworthy paper on "Dopes and Detonation," by Prof. H. L. Callendar, Capt. R. O. King, and Flight-Lieut. C. J. Sims (*Engineering*, April 9, 1926, p. 475): "The patentees recommend, however, that the mixed dope called 'Ethyl fluid' should not be used in a greater proportion than 5 c.c. per gallon, each 5 c.c. containing 3 c.c. of lead ethide, which, according to the A.M.L. tests, would permit an increase of compression ratio of about 10 per cent. The importance of this limitation has recently been confirmed by an endurance test of 100 hours on a Napier Lion engine of 450 h.p. at the Royal Aircraft Establishment. . . . Shell Aviation spirit was used for the first 50 hours with 5 c.c. per gallon of the normal ethyl fluid. For the second 50 hours B.P. Aviation spirit was employed with 5 c.c. per gallon of ethyl fluid, containing a larger proportion—namely, 2·5 c.c. of ethylene dibromide—the content of lead ethide being 3 c.c. in both cases. . . . After 50 hours, the spark-plugs showed heavy deposits of lead salts and high leakage of gas through the mica. After 100 hours these defects were intensified. All plugs showed signs of having been severely over-heated, and the deposits of salts formed an easy flash-over path. Three cases of punctured mica were noted, which would render the plugs useless in an engine."

These results have been confirmed in varying degrees in motor-car engines, but all engines do not show anything like the same susceptibility, and there is no doubt that the conditions of operation play an important part.

I am not free at present to discuss this subject here as fully as I might otherwise wish, but I feel justified in commenting on one further point in Dr. Mardles' article. Under the heading "Compression and Efficiency," it is stated that "considerable progress can be made with the use of higher compression ratios involving an annual saving in the aggregate of many million pounds sterling." This statement is amenable to simple arithmetical examination. Assuming a compression ratio of 5 to 1 for straight petrol and 5·5 to 1 for ethyl petrol—an increase of 10 per cent.—we find by interpolation from Table I. on page 424, that the indicated thermal efficiency would increase from 32·8 per cent. for straight petrol to 34·5 per cent. for ethyl petrol, an increase (theoretically) of 5·2 per cent. This increase is obtained at the expense of the added anti-detonants, and if these cost more than 5·2 per cent. of the fuel, there is 'in the aggregate' a loss. As a matter of fact, the present cost of doped fuel is 1*d*. per gallon more than the equivalent straight petrol, an increase of 1 in 14·5 in the London area, or 6·9 per cent. It is clear, therefore, that with existing prices, a motorist who raised his compression ratio by 10 per cent. in order to utilise the properties of the new fuel, would incur a loss in fuel costs alone of 1·7 per cent.

H. S. ROWELL.
(Director of Research.)

Research Association of British
Motor and Allied Manufacturers,
15 Bolton Road,
Chiswick, W.4, Mar. 19.

THE observations made by Mr. Rowell that deposits in an engine after running on ethyl petrol are subject to considerable variation in quantity and kind are certainly true. This is indicated by the two analyses given in Tables IV. and V., the first made in Great Britain and the second in the United States. Naturally, the lead content would vary with engine conditions and would appear less, for example, with a high degree of carbonisation. There is also no significance between the amount of lead used and found respectively. Thus, the amount of final lead deposits from cars that have actually run 40,000 miles on ethyl petrol would bear only a small proportion to the 12 lb. of lead consumed, whilst with a car run for an hour on ethyl petrol the proportion would doubtless be higher.

The conclusion given in the article, that the results of prolonged engine trials confirm the claims made that ethyl petrol would not injure engine parts, was based in part on the extensive experience of motor-car manufacturers in the U.S.A. and of the U.S. Naval Air Service, which uses ethyl petrol almost exclusively for fuel.

The quotation made by Mr. Rowell from a paper by Prof. Callendar, Capt. R. O. King, and Flight-Lieut. Sims relates to early experiments on the behaviour of ethyl petrol in an aero engine, but subsequent research with lead tetraethyl in air-cooled aero engines can be summarised in the statement that after one hundred hours' run no ill effects on the engine were shown (*Jour. Roy. Aero. Soc.*, 30, 731; 1926).

In spite of Mr. Rowell's calculations that the use of ethyl petrol is uneconomical, I still maintain that with the use of higher compression ratios there would be an annual saving in the aggregate of many million pounds sterling. This statement is independent of the increase in compression ratio obtainable with any particular petrol or engine, and it must be remembered that lead tetraethyl is but the first successful 'anti-knocker'; future research may yield others which it is hoped will enable the motor engineer, by removing restrictions due to fuel failings, to operate at a compression ratio in the neighbourhood of 7 : 1.

E. MARDLES.

The Non-Appearance of the Recombination Luminescence in the Reaction between Alkali and Halogen Atoms.

FROM the possibility of a direct dissociation of salt molecules of NaCl type in the non-charged normal atoms by the light action (Franck, Kuhn u. Rollefson, *Zs. f. Phys.*, 43, 155; 1927) follows another possibility—*a direct recombination* of the alkali and of the halogen atoms in a salt molecule, followed by a continuous light emission. All attempts to find this recombination spectrum have been without result. The chemiluminescence spectra emitted in the reaction between alkali atoms and the halogens have nothing to do with the continuous bands known as the absorption bands of the salts in question.

These negative experimental results make it necessary to look for another mechanism of the building of the heteropolar molecules of this type instead of that of the inversion of dissociation. Some investigations on the chemiluminescence permit us to outline such a mechanism. From Polanyi's and his collaborators' investigations we can assume with considerable certainty that the reaction $Na + Cl_2$ in the gas phase follows the scheme:

$$
\begin{aligned}
Na + Cl_2 &= NaCl + Cl \\
Cl + Na &= NaCl^{\cdot} \\
NaCl^{\cdot} + Na &= NaCl^{\cdot} + Na' \\
Na' &= Na + h\nu.
\end{aligned}
$$

In this scheme the exciter of the chemiluminescence (in this reaction an intense line spectrum of sodium is observed) is a molecule $NaCl^{\cdot}$, which has an excess of energy. The great intensity of the chemiluminescence suggests that the exciter ($NaCl^{\cdot}$) must exist a sufficiently *long time* as an energy-rich molecule to meet a sodium atom. Such a long living molecule could be a *dipole* $\overset{+}{Na}\overset{-}{Cl}$, which is formed by the recombination of the sodium and chlorine atoms, and *gradually* loses its excessive energy of vibration by the emission of infra-red radiation quanta (Kondratjew, *Zs. f. Phys.*, 45, 67; 1927).

We shall now see in what way such a recombination can occur. Plotting the potential energy E of the system atom-atom and then that of the system $\overset{+}{\text{ion}}$-$\overset{-}{\text{ion}}$ as a function of the distance r between two nuclei, we obtain two curves, which in the case of all heteropolar diatomic salt molecules *give an intersection* at a smaller or greater distance r_v. Such curves are represented in Fig. 1 (here J is the $\overset{+}{\text{ion}}$-$\overset{-}{\text{ion}}$ curve, A the atom-atom curve). At the intersection (r_s) the energies of the system $(Me)\ (X)$ and of the system $(\overset{+}{Me})\ (\overset{-}{X})$ are *equal*. At this point the valency electron of the metal can be 'adiabatically' transferred to the halogen atom, *i.e.* a transformation $(Me)\ (X) \rightarrow (\overset{+}{Me})\ (\overset{-}{X})$ can occur. This mechanism of the building up of NaCl was proposed by the author in the discussion on chemical kinetics in the first Physico-Chemical Conference in Leningrad in February 1927 (published in *Communications on the Scientific and Technical Works in the Republic*, vol. 23, Leningrad, 1927). The possibility of the transition $(A)\ (B) \rightarrow (\overset{+}{A})\ (\overset{-}{B})$ is also suggested by F. London (London, *Zs. f. Phys.*, 46, 455; 1928).

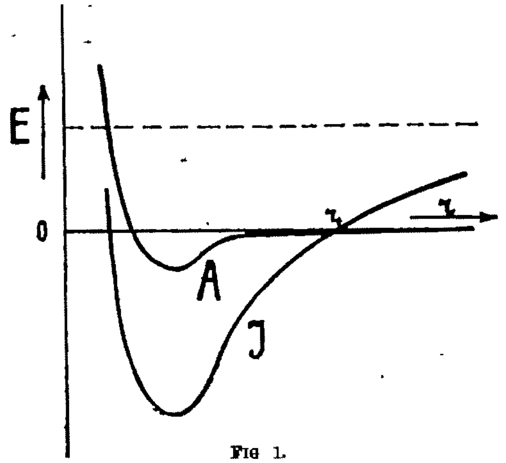

FIG 1.

The molecule $\overset{+}{Me}\,\overset{-}{X}$ $(Me\,X)$, formed in this way from the neutral atoms, can therefore exist for a comparatively long time in a high vibrational state. The energy of vibration of such a molecule can be increased by the absorption of the temperature radiation, to a quantity $Q + J - E$ (Q is the heat of reaction $Me + X = MeX$, J the ionising potential of the cation and E the electron affinity of the anion). It is quite possible that this circumstance explains the appearance in the chemiluminescence spectrum of lines the excitation energy of which considerably exceeds the reaction heat (Q).

As to the transitions $(A) \rightarrow (J)$ at the distances $r < r_s$ we can here expect *a priori* a spontaneous transition followed by emission of light. The wavelengths of this radiation should be determined by the probabilities of the corresponding transitions. The absence of visible radiation in the reactions in question evidently suggests that the probability of the transition $(A) \rightarrow (J)$ at r_s and in the neighbouring points is very considerable.

Then we can expect the radiation in the case of recombination of one normal and one excited atom, the curves $(Me')\ (X)$ or $(Me)\ (X')$ and $(\overset{+}{Me})\ (\overset{-}{X})$ of which do not intersect. It is very interesting, that in the chemiluminescence spectrum of the reaction $\mathrm{K} + \mathrm{I}_2$, a large continuous band is observed, but it is not observed in the case of the reaction $\mathrm{Na} + \mathrm{I}_2$ (Ljalikoff u. Terenin, *Zs. f. Phys.*, 40, 107; 1926). At the same time the curves (K) (I) and $(\overset{+}{\mathrm{K}})\ (\overset{-}{\mathrm{I}})$ do not intersect ($J_K - E < A_{\mathrm{I}}$, $A_{\mathrm{I}} = 2^2p_2 - 2^2p_1$ is the excitation energy of the metastable level of the iodine atom) and the curves (Na) (I′) and $(\overset{+}{\mathrm{Na}})\ (\overset{-}{\mathrm{I}})$ do intersect.

Science Teaching in Schools.

I SHOULD like, if I may, to make a few observations, as briefly as possible, on the recent correspondence in NATURE on this subject.

If any discussion is to materialise, two things may safely be taken for granted, namely, that there is likely to be much diversity of opinion, and that the bulk of that opinion will be in favour of modification rather than revolution. 'The inevitability of gradualness' applies here; and it may reasonably be urged (*a*) that the present system is not altogether devoid of good qualities, and (*b*) that the scientific attitude, which is far more important than mere book knowledge, may be acquired in any branch of science, whether physics, chemistry, or biology. I think we may assume that at present the abolition of the 'subject' system is impracticable, even if it were desirable. There are some who fear, not without justification, that too extended a course of elementary science tends to degenerate into what the Rev. Dr. Folliott stigmatised some years ago as "everything for everybody, science for all, schools for all, rhetoric for all, law for all, physic for all, words for all, and sense for none."

Again, it would be unfortunate if by any means, democratic or despotic, too exact a syllabus were to be imposed upon schools. We all have our own ideas, and teach best those things in which we are most interested. My plea is for greater liberty in this respect, and for more time in which to deal with essential mental and manipulative processes; and these can only be gained if the university examiners agree to modify their demands. They could easily do this, if they chose, and could thereby succeed in distinguishing between boys of real ability and those who had merely crammed far more efficiently than at present.

I have reason to believe that the suggestion was made last year that some of the university examiners should meet the Science Masters' Association in London, and that the examiners themselves were willing, and even anxious, to do so. It would be interesting to know on what grounds so desirable a step was frustrated.

A. K. GOARD.

Marlborough College, Wilts, Mar. 25.

FROM the recent correspondence which has appeared in NATURE on the teaching of science in schools, the most striking impression I have obtained is that on a problem which one would expect to be perfectly straightforward, opinions differ enormously. In other words, it is evident that those people who are now engaged in teaching science do not themselves know, as a body, what their aims and objects are, and what are the best methods necessary to attain them. Controversy is always stimulating, but when it arises from such a wide range of opinion it tends to hamper progressive movement, and has a bad effect on those people who in perfect good faith listen to each expert in turn.

As one who has taught many branches of elementary science for some years, it seems to me that the relations of school and university play at present a dominating rôle in the science taught at schools, and the influence is not all to the good. The main object of schools seems to be to produce scholarships, and the main objects of universities to produce research workers. Such objects have a cramping effect on the whole organisation of science teaching. In the first place, very many boys from public and secondary schools never go near a university; and secondly, only a relatively small proportion of students who do go there become first-class research workers. The really good research worker survives under almost repressive conditions, and is often hampered by the people whose job it is to teach him. When research is so badly paid it seems a pity that it should be held up as an ideal to any students but the very best, especially since progress in the applications of science only partly keep step with the rate at which discoveries are made, as the modern system of agriculture in England shows very clearly.

The great mass of boys and students do not possess the research mind, and no amount of training in method will give it to them. In their scientific education they slowly, and often painfully, acquire some technical knowledge, most of which is of no further value when the examination is over. Pushing them hard merely dulls their wits and gives them a bad taste for science. They lack the imagination required for research, and the technical ability to handle apparatus with real success. They do, however, make up the bulk of those people who control our complex industrial system, because they possess general ability and character for leadership.

My personal complaint is that, while science has now illuminated the western world for some hundred years, no bold attempt has yet been made to reorganise and direct our social system in keeping with it. It has been given no cultural value, although it has had a profound and disturbing effect on all previous types of culture and æsthetic ideals. As a new force it yet lacks 'official' recognition except in Central and Eastern Europe, where it is beginning to affect art, literature, and possibly music. The coming of science and industry has completely changed the world. It has given us social, economic, and international, problems which cry aloud for scientific solutions; but unless the mass of the people is trained in the atmosphere of science, it will persist in attempting to solve these problems on traditional medieval lines. In this respect there is an enormous field for our educational institutions, which still waste time teaching the difference between density and specific gravity, and the number of stamens in a flower, in jargon which has been invented to make the task difficult. At present science as taught, with exceptions of course, is in the 'date' stage of history or the 'capes and peaks' stage of geography. It will only gain respect as an educational medium when it has set up cultural ideals which are attractive to all types of thinkers. Of course, evolution in the right direction is inevitably taking place in spite of efforts to prevent it, but we could accelerate the change considerably if we really pulled together.

R. Weatherall.

Eton College, Windsor, Mar. 28.

Beats by High-Frequency Interruption of Light.

For some time past we have been engaged in developing a compact laboratory method of measuring the velocity of light by utilising the Kerr electro-optic effect in nitrobenzene for obtaining very rapid intermittence in a light beam. The restoration of light by nitrobenzene (put between crossed Nicols) under electric stimulus is comparatively large and is almost instantaneous—the lag being of the order of 10^{-10} sec.

The Kerr cell employed was of the type developed by Karolus (for the Telefunken-Karolus system of picture transmission), and was kindly supplied to us by the Telefunken Company.

As in all such experiments for velocity determination the light has to be passed twice through the interrupting mechanism, it was thought desirable, as a preliminary step, to see if sufficient light would come out through two cells in succession. After overcoming considerable experimental difficulties, and by using sunlight as source, we were able to get sufficiently intense interrupted light passing out of the second cell. To test if the interruptions were taking place properly, the sunlight was focused on the first Karolus cell placed between crossed Nicols and excited by a valve-maintained oscillator of frequency about 10^6 cycles per second. The restored intermittent light was received on a second cell excited by another oscillator, differing in frequency from the first by a few hundred cycles. The emergent light, after passing through another Nicol, was received in a fall-plate camera, and the slow light beats resulting from the interference of the high-frequency interruptions in the two cells were photographed. Fig. 1 is a reproduction of such a photograph magnified three diameters.

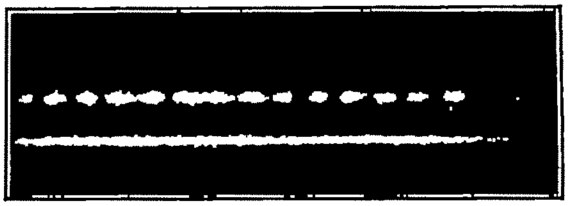

Fig. 1.

The frequency of the light beat was apparently double the frequency of the heterodyne beat note as heard in a telephone. We attempted to detect the light beats visually by bringing down the beat frequency to two or three per second. In this we were unsuccessful, obviously due to the forced synchronisation of the two oscillations (as noticed by Appleton, *Proc. Camb. Phil. Soc.*, vol. 21; 1922) taking place long before the difference in the frequencies becomes sufficiently small to make visual observation possible.

This beat method can be adapted to study the high-frequency interruption of light by resonating quartz, which Prof. Kerr Grant tried to photograph at a frequency of 144 kilo-cycles per second, but was unsuccessful (Nature, Oct. 22, 1927). It is only necessary to replace the first or the second Karolus cell by the resonating quartz. In his note, Prof. Kerr Grant suggests the employment of resonating quartz for obtaining interrupted light of very high frequency up to ten million per second. We are doubtful if this is practically possible. The thickness of a quartz crystal cut and ground to this frequency is very small (only a fraction of a millimetre along the electrical axis and normal to the optic axis, for it is about one millimetre even for a million-cycle) and it would be exceedingly difficult, if not impossible, to make any observation by passing light in a direction parallel to the optic axis.

The Nature and Function of Golgi Bodies.

Prof. Gatenby says (Nature, Mar. 24): "Prof. Walker's original position was that *both categories of the cytoplasmic inclusions* [mitochondria and Golgi bodies] *are artefacts*. In his printed paper he merely claims that the Golgi bodies alone are artefacts." My "position" was, continued to be in my "printed paper," and still is, that *some of* the bodies claimed as mitochondria in fixed material are artefacts; and that those among the appearances claimed as Golgi apparatus, the presence of which in the cell cannot be accounted for without assuming the existence of this peculiar "organella," as Prof. Gatenby calls it, are artefacts. Thus it would seem that either he has not read what I have written, or that he is misquoting what he has read.

Both Prof. Gatenby and Dr. Ludford make much of the constant positions taken up by the Golgi apparatus in similar cells. Our knowledge of the chemistry of the cell is so limited that it is impossible to explain in many cases the position taken up by the separated lipins in different cells. I have, however, nearly ready for publication, an account of conditions in which my Golgi bodies may be made to take up a constant position in relation to the artificial nuclei in my mixtures, conditions which may well be produced by the nucleus of the living cell in certain circumstances.

I believe that all microscopic observations upon fresh cells removed from the living body of the multicellular animal should be accepted with caution. Changes must begin at once even under the most favourable conditions. It does not appear to me that the technique of the demonstrators of the Golgi apparatus "takes into account our biochemical knowledge of the solubilities of lipoids and other subtle cell bodies" as Prof. Gatenby says they do. The facility with which the colloids of the cell, more particularly perhaps the lipins, may be separated from each other and from the water with which they are associated, seems to be entirely ignored. Temporary separation might well occur under normal cell conditions, which would be rendered permanent by certain abnormal ones

The formation of artefacts has been much neglected during recent years. They constitute perhaps the most dangerous pitfall for the cytologist. I cannot enter into the theory and practice of fixation and other processes, but for Prof. Gatenby's information would point out that maceration of material, among many other modes of treatment, is sure to distort the cells and their contents very seriously. What Prof. Gatenby would have us believe is "modern cytological technique" seems to be largely confined to those who demonstrate what he calls "cytoplasmic inclusions" and to neurologists.

If I were, as I certainly am not, the only cytologist living who did not believe in the "Golgi bodies," I fail to agree with Prof. Gatenby that this in itself would be a proof that I was wrong. Much greater men than he or I have occupied that invidious position in the past, and have proved right in the end.

May I point out that I still seek in vain for even a hint as to the function of the "Golgi bodies," which are assumed to exist as definite structures in all the cells of all animals and many plants. Also I have failed to extract information as to what becomes of the lipins in the cells that are treated by the "Golgi apparatus" methods.

I did not write of the archoplasm but of structures contained in it, and pointed out that these had been found in every animal investigated. Dr. Ludford's definition of the Golgi apparatus as a specialised area in the cytoplasm does not seem to agree with Prof. Gatenby's "batonettes." I would refer them both to D. Tretjakoff's paper, *Zeits. f. Zellforschung u. Mikro. Anat.*, Abt. B, 7 Band, 1 Heft., Feb. 1928.

Prof. Gatenby's naïve attitude that the value of his own interpretation of observations is increased by frequent repetition, and that he has reached the limits of cytological technique, reminds me of the Bellman in "The Hunting of the Snark."

> "Just the place for a Snark! I have said it thrice:
> What I tell you three times is true."

Charles Walker.

The Inner Photoelectric Effect with Silver Halides.

Consideration of the energy steps in the Born cycle for calculating the lattice energies of the silver halides leads to the following conclusions:

1. The photolysis of solid silver halide might occur *directly* to give halogen and metallic silver. This requires only a quantum at 8000 A. or longer, equivalent to the heat of formation of the halides from the elements.

2. This photolysis might occur *indirectly*, by way of separation of electrons from halide ions, followed by acceptance of the electrons by silver ions. This course would require (1) a quantum at $\lambda = 1300$ A., or beyond, to disrupt the lattice, then a quantum at $\lambda = 3000$ A., or beyond, to liberate electrons. In subsequent reactions, of electron acceptance, etc., energy might be freed, either as radiation quanta or by radiationless collisions, so that the final difference of energy equals the heat of formation. However, in this case (2) primary absorption of two quanta appears necessary, at thresholds much higher than those known to be operative in the photochemical decomposition of the silver halides.

Obviously, the contradiction might be simply dismissed by abandoning the view that the photolysis involves the intermediate liberation of photoelectrons from halide ions—a hypothesis suggested independently by K. Fajans and by the writer. But the phenomena of photoconductance definitely point to a relative freeing of photoelectrons, and Dr. F. C. Toy has shown (Nature, Sept. 24, 1927) that the discrepancy between the photoconductance absorption spectrum of the silver halides and the spectrum photographically active is removed by consideration of the thickness factor. Moreover, recently Dr. W. Vanselow and the writer have obtained independent evidence of the liberation of photoelectrons, *concomitant with the production of free halogen*, in a study of the photopotentials of silver–silver halide electrodes in electrolytes.

The difficulty of the energy quanta required cannot be dismissed therefore. The experimental evidence obtained with these cells has led to a modified theory of the inner photoelectric effect which is consistent with the writer's orientation theory of photographic sensitivity and latent image formation. By considering that both the lattice energy and electron affinity are lowered at interfaces, particularly at true interfaces with conductors, it seems possible for the inner photoelectric effect to occur at the lower wavelengths in question.

An interesting corollary is a possible relation of this to the theory of E. A. Baker (Nature, May 7, 1927, p. 685; *Proc. Roy. Soc. Edin.*, 47, 34; 1927), that "*two* quanta are concerned in photographic action, and that the two must be absorbed within a short interval of time, giving the effect of two distinct absorptions when the exposure is short, and of simultaneous absorption when the exposure is long. This indicates that in the absence of a second absorption the effect of the first quantum is transitory, the action being of the type

$$A + h\nu \rightleftharpoons A'$$
$$A' + h\nu \longrightarrow A''.\text{''}$$

If we regard the first quantum as necessary to loosen the lattice (to overcome lattice energy) and the second to release the photoelectron from the halide ion, it will be seen that the considerations advanced may support Dr. Baker's theory of reciprocity failure.

It is hoped to publish the discussion of lattice energy at an early date, and the study of the inner photoelectric effect in relation to latent image formation somewhat later. S. E. SHEPPARD.

Vision and Reality.

IF a philosopher may be permitted to take part in a discussion which seems to involve questions of scientific import alone, I would like to point out certain ideas which bear upon the problem of whether the eye has been so adapted as best to use the energy of sunlight. Sir John Parsons suggests (NATURE, Jan. 21, p. 94) that this conclusion is consistent with the fact that the brightest part of the spectrum (of the luminosity curve) coincides with the summit of the curve of radiant energy. But Mr. T. Smith (NATURE, Feb. 18, p. 242) presents another view—not inconsistent with the foregoing conception—in which vision is held to be so constituted as to bring out the sharpness of contours of bodies. This conclusion, while very important, does not seem to me to be especially novel. Prof. Eddington, in his "Stars and Atoms," also suggested that we have in the coincidence of the peak of the visibility curve with the peak of the curve of radiant energy an interesting case of evolutionary adaptation. But aside from these views, Bergson, it might be argued, had proposed something of the sort in his notion of the 'geometrising intellect.' This, at any rate, would be the case if the interpretation which the present writer puts on Bergson is the true one.

In presenting to my students in philosophy the 'problem of reality,' I have for several years employed the practice of pointing out the ways in which our knowledge of the external world is prejudiced by experiences to which our sense organs give rise. I have then always raised the question of how the world would appear if some of the limitations of our senses were overcome. More specifically, how would the world appear if our eyes were so constituted that we could see in the ultra-violet or the infra-red ends of the spectrum? If we could see in the infra-red end, bodies which are not in thermal equilibrium with their environments would then seem to be surrounded by a halo due to the heat rays which were being given off by the radiating bodies. In the same way, if we saw in the ultra-violet, all objects which give off these waves (for example, mercury) would be surrounded by a penumbra. This suggests the conclusion that the apparent sharpness of boundary of some objects is due to the structure of the human retina, that is, to the fact that vision is best in the yellow region of the spectrum.

This fact that sense experience (both in vision and in tactual experience, in so far as sight is 'anticipative touch' and tactual perceptions are synthesised with visual space) exaggerates the sharpness of contours, may be responsible for the sharp opposition between 'matter' and 'empty space.' The intellectual distinction between matter and energy may be a result of the fact that the eye, the organ of vision, is a direct outgrowth of the brain, the organ of thought. It is interesting to note that the 'quantum puzzle' is not being solved by making light corpuscular, but by making matter undulatory. In other words, perhaps the problems in some branches of science will be solved by unlearning some of the cerebral reactions or ideas which developed around sensory experience. Perhaps when we have become accustomed to Schrodinger's notion of substance as a set of wave-patterns, the idea of matter as something eternally and absolutely distinguished from energy-fields will be relegated to the science of mental palæontology as a fossil of human thought. 'Sports' and 'Reversion.'

THE note on Dr. C. J. Bond's Galton Lecture, which appeared in NATURE of Feb. 25, contains the following remarkable sentence (p. 292): "He [*i.e.* Dr. Bond] did not reflect, however, that 'sports,' although hereditary, must owe their origin to definite causes, and that the evidence before us justifies the belief that when these causes cease to operate the 'sport' ultimately reverts to the wild type."

It is, of course, true that sports must owe their origin to definite causes; but it is equally true that we know nothing whatever as to the nature of the causes underlying mutation. How, then, are we to know when such causes "cease to operate"? Further, it would be interesting to know what the evidence in favour of the 'reversion' of sports may be. *Chelidonium laciniatum* Miller, perhaps the best authenticated of mutants, has certainly not been observed to revert during the 338 years for which it has been known to science. The other mutants of known date of origin have shown a similar constancy. Indeed, it might be said to be characteristic of true seminal mutants that they do *not* revert.

If I am not mistaken, the only phenomenon which the geneticist would care to call 'reversion,' even by courtesy, is that exemplified by the appearance of a definite proportion of red-flowered plants among the segregates from a cross between an ivory-flowered snapdragon and a white-flowered snapdragon of a particular genetic constitution. In such a case the appearance of the supposedly ancestral type—in this instance the red-flowered plant—is a necessary consequence of the mating of particular gametes, and is quite independent of the incidence of environmental factors.
